Summary

Leaf senescence is an active process required for plant survival, and it is flexibly controlled, allowing plant adaptation to environmental conditions. Although senescence is largely an age-dependent process, it can be triggered by environmental signals and stresses. Leaf senescence coordinates the breakdown and turnover of many cellular components, allowing a massive remobilization and recycling of nutrients from senescing tissues to other organs (e.g., young leaves, roots, and seeds), thus enhancing the fitness of the plant. Such metabolic coordination requires a tight regulation of gene expression. One important mechanism for the regulation of gene expression is at the transcriptional level via transcription factors (TFs). The NAC TF family (*NAM*, *ATAF*, *CUC*) includes various members that show elevated expression during senescence, including *ORE1* (*ANAC092/AtNAC2*) among others. *ORE1* was first reported in a screen for mutants with delayed senescence (*oresara1*, *2*, *3*, and *11*). It was named after the Korean word “oresara,” meaning “long-living,” and abbreviated to *ORE1*, *2*, *3*, and *11*, respectively. Although the pivotal role of *ORE1* in controlling leaf senescence has recently been demonstrated, the underlying molecular mechanisms and the pathways it regulates are still poorly understood.

To unravel the signaling cascade through which *ORE1* exerts its function, we analyzed particular features of regulatory pathways up-stream and down-stream of *ORE1*. We identified characteristic spatial and temporal expression patterns of *ORE1* that are conserved in *Arabidopsis thaliana* and *Nicotiana tabacum* and that link *ORE1* expression to senescence as well as to salt stress. We proved that *ORE1* positively regulates natural and dark-induced senescence. Molecular characterization of the *ORE1* promoter *in silico* and experimentally suggested a role of the 5'UTR in mediating *ORE1* expression. *ORE1* is a putative substrate of a calcium-dependent protein kinase named CKOR (unpublished data). Promising data revealed a positive regulation of putative *ORE1* targets by CKOR, suggesting the phosphorylation of *ORE1* as a requirement for its regulation. Additionally, as part of the *ORE1* up-stream regulatory pathway, we identified the NAC TF *ATAF1* which was able to transactivate the *ORE1* promoter *in vivo*. Expression studies using chemically inducible *ORE1* overexpression lines and transactivation assays employing leaf mesophyll cell protoplasts provided information on target genes whose expression was rapidly induced upon *ORE1* induction. First, a set of target genes was established and referred to as early

responding in the ORE1 regulatory network. The consensus binding site (BS) of ORE1 was characterized. Analysis of some putative targets revealed the presence of *ORE1* BSs in their promoters and the *in vitro* and *in vivo* binding of ORE1 to their promoters. Among these putative target genes, *BIFUNCTIONAL NUCLEASE 1 (BFN1)* and *VND-Interacting2 (VNI2)* were further characterized. The expression of *BFN1* was found to be dependent on the presence of *ORE1*. Our results provide convincing data which support a role for *BFN1* as a direct target of *ORE1*. Characterization of *VNI2* in age-dependent and stress-induced senescence revealed ORE1 as a key up-stream regulator since it can bind and activate *VNI2* expression *in vivo* and *in vitro*. Furthermore, *VNI2* was able to promote or delay senescence depending on the presence of an activation domain located in its C-terminal region. The plasticity of this gene might include alternative splicing (AS) to regulate its function in different organs and at different developmental stages, particularly during senescence. A model is proposed on the molecular mechanism governing the dual role of *VNI2* during senescence.

Acknowledgments

During these past few years I have one of the most enriching times of my entire life. I growth as a science person, I proved my capacities, my patient, my limits and my self-confidence. I learned the real value of my friends, my family and the simple things of life that I left in my country Colombia. The most valuable knowledge is not only the one that I learn as a molecular biologist is the one that help me to improve my life to become a better person and reinforces my moral and my ethics. Nevertheless, none of this valuable life lessons would have been possible without the friendship and encourage of all my friends, family and supervisors.

I would like to acknowledge my Ph.D supervisors, Prof Dr. Bernd Mueller-Roeber and Dr. Salma Balazadeh for giving me the opportunity to make my Ph.D thesis in the group and introduce me in the fascinating world of plant molecular biology, let me grow as a scientist. I want to thank the DAAD (Akademischer Austausch Dienst) for the financial support, the opportunity to learn another language and the facilities to integrate me into the German culture. I am heartily thankful to the DAAD representative for Latin America, Arpe Caspary for his friendship, for believing in me and my capacities. I wish also to thank the former Colombia referat Mrs. Silke Hamacher for her efficient work and nice attitude.

I want to thank exclusively Dr. Judith Lucia Gómez-Porras. She careful read and editorial assisted my thesis. She established with me nutritive scientific discussions and her criticisms, support and humor were the most powerful inputs to complete successfully the final level of my Ph.D. I want to thanks Dr. Alex Ivakov and Matt Neville to point key aspects to improve the document. I want to thanks Dr. Francesco Licausi for stimulating discussions of the experiments, improvements on the document and his unconditional friendship. I received thoughtful suggestions, discussions and warm spiritual support from my Ph.D committee members Prof. Dr. Ingo Dreyer and Dr. Dirk Hinch. All of them directed me become a good scientist.

I would specifically like to thank Dr. Eugenia Maximova who always takes the time to help me in microscopy, Dr. Karin Köhl and her Greenteam especially Linda Bartetzko, Katrin Seehaus, Sven Roigk, Helga Kulka, Britta Hausmann and Katrin Lepa for taking excellent care of plants and transformations and giving me always a smile and good advices; Josef

Bergstein for the excellent photography work and nice conversations. Many thanks go also to the IT team; the administration team and the media kitchen for making my time at the MPI-Golm better and efficient.

I want to thank all members of the Molecular Biology Department at the University of Potsdam especially Mathias Christoph, Eike Kamman, Dr. Dagmar Kupper, Antje Scheneider, Karina Schulz, Radoslaw Lukoszek, Dr. Minh Hung Nguyen and Ines Nowak for guiding me and teach me key aspects for my daily lab work. Also thanks for their friendship and be always open to help me. I also want to thank Nooshin Omranian, Mamoona Rauf, Arif Muhammad, Prashant Garapati and Amin Omidbakhshfard for their support.

My especial appreciation goes to my collaborators; Prof. Dr. Amnon Lers (Volcani Center, Israel), Dr. Gang-Ping Xue (CSIRO Plant Industry, Australia) and Prof. Dr. Wolfgang Dröge-Laser (Julius-Maximilians-Universität Würzburg) for excellent discussions and improvement on the article.

I also keep in my hearth grateful my friends Daan Weits, Dr. Federico Giorgio, Anna Flis, Monika Chodasiewicz, Asdrubal Burgos, Rodrigo Caroca, Ignacia Bustos, Susana Salem, Dr. Sonia Osorio, Dr. Clara Sanchez, Phuong Anh Pham, Dr. Dimas Riveiro, Soledad Garcia, Dr. Samuel Ardvison, Dr. Martin Lauxmann, Romy Schmidt, Dr. Josefus Schippers, Claudia Sanabria, Justyna Tomala, Raul Trejos, Maryory Leyton, Niels Weisbach and Katharina Berger. All of them support me through my Ph.D taking me out of my routine, improving my research and making my life much happier and easier.

I offer my most sincere gratitude towards Dr. Flavia Vischi, Dr. Fernando Arana, Dr. Diego Riaño-Pachón, Dr. Magarita Perea-Dallos and Dr. Nestor Riaño my close friends for their sincere support and because without your continue positivism and encourage it would have been impossible for me to begin and complete this work successfully.

Special thanks to Family Brozio, Family Lieutenant, Family Peña-Andrade and Andrea Diaz for making me feel at home in Germany.

The impulse to embark into this adventure and the encouragement and love to go to the end comes from my beloved friend and partner Hernando Leyton. He has never accepted less than my best efforts. Thank you.

Lastly, I offer my deepest regards and blessings to my whole family especially to my beloved mom Cristina, my young brother Alejandro, Emilse, Anitilde and Sebastian who supported me, shared with me all the stresses and teach me the most important values in life.

Chapter 1

Introduction

1.1. General concepts of plant senescence and its regulation

The process of aging and senescence in humans and plants has been the focus of major studies for a long time (Breeze *et al.*, 2011; Howard *et al.*, 2009; Kirkwood and Austad, 2000; Lim *et al.*, 2007; Thomas 2002). A primary motivation for this is to understand what controls the decline of tissue and organ functionality and reproduction ability when higher organisms age, and which factors determine the length of life. Certainly, both aspects have a broad spectrum of explanations ranging from an inherent genetic control present in each organism to external factors such as environmental conditions and natural selection. In the following, I will give an overview of current knowledge with respect to the physiological process of senescence in plants.

Two major theories of senescence are currently acknowledged and have been developed mainly in the animal field: the antagonistic pleiotropic theory and the mutation accumulation theory. Both theories suggest that two classes of mutations are responsible for senescence: those with beneficial early-life, but deleterious late-life effects; and late-acting mutations with purely deleterious effects (Jing *et al.*, 2007; Kirkwood and Austad, 2000). In animals and yeast, those theories have been well demonstrated based on physiological and molecular studies on individuals at the population and species levels (Kirkwood and Cremer, 1982; Williams, 1957). Plants exhibit modular growth, exposes a propensity for vegetative reproduction, and can begin senescence in one or more organs at different times throughout the life-span of the plant. Without doubt, senescence in plants exposes particular features that do not fit well into these theories (Bleecker, 1998). In an effort to reconcile the theories about animals with plants, some authors have proposed to scale them down and treat an individual leaf as an autonomous entity (Thomas, 2002). I agree with the concept that has already been exposed by different authors in which leaf senescence is conceived as a detrimental consequence of an indirect selection for traits that favor nutrient salvage, remobilization, and reassimilation to optimize the plant genome for reproduction (Bleecker, 1998; Jing *et al.*, 2007). This highly regulated and orderly process controls an efficient redistribution of

valuable resources (especially nitrogen and carbon) to other developing organs (Bleecker, 1998; Breeze *et al.*, 2011; Buchanan-Wollaston 1997; Gan and Amasino, 1997).

The concepts described above are complemented by the fact that leaf senescence can be influenced by hormonal and developmental processes and is fuelled by experimental and modeling assays in which a differential expression of genes is evident among the whole process (Buchanan-Wollaston, 1997; Pontier *et al.*, 1999). Despite the fact that plants suffer drastic ultrastructural changes during the breakdown of chloroplasts, a decrease of cytoplasmic volume and ribosomes, and the dismantling of various organelles, other cellular entities remain largely intact initially to guarantee effective gene expression and energy production during the senescence process. Thus, the plasma membrane, mitochondria, and the nucleus remain intact until the latest senescence stages (Gan and Amasino, 1997). Apart from environmental nutrition deficiency and other stresses, plants ultimately initiate and progress leaf senescence in an independent manner. *Arabidopsis thaliana* is a monocarpic model plant, in which senescence is controlled by the reproductive structures. The seeds are being produced while the plant starts to senescence, reusing the storage nutrients from photosynthetic tissues (Gan and Amasino, 1997).

During the reassimilation and dismantling process, plants exhibit a strong biochemical activity to degrade most of the macromolecules such as chlorophyll, proteins, and lipids. Later, different strategies are used to modulate the progression of senescence, like hormonal changes and redistribution of the metabolic flux, particularly with respect to nitrogen and sugars (Lim *et al.*, 2003; Liu *et al.*, 2008; Noodén and Guiamet 1996; Otegui *et al.*, 2005; Quirino *et al.*, 2000).

Following this line of argument, the functional characterization of senescence-regulatory networks and their underlying genes represents an appropriate way to further discern the ongoing processes during senescence. In addition, such an approach will allow studying senescence from a cross-kingdom phylogenetic view and will likely add to our understanding of the evolutionary paths through which senescence developed.

1.2. Dismantling of chloroplasts

Chloroplasts break down early during the senescence process, prior to the loss of mitochondria and nuclei (Lim *et al.*, 2007), and concomitantly undergo a progressive decrease in photosynthetic rate. The major fraction of nitrogen (70-90%) exported from senescent leaves comes from the degradation of Rubisco, light-harvesting chlorophyll a/b-binding proteins, and proteins from Photosystem II (PSII) and Photosystem I (PSI) which are located in the stroma and thylakoid membranes (Morita, 1980). During chloroplast formation in young, growing leaves, pigments and proteins are assembled as active and interacting complexes; therefore, the dismantling of these complexes during senescence

is a prerequisite for the enzymatic degradation of the individual components. A series of characteristic events can be observed during senescence using electron microscopy, x-ray diffraction, and immunological and fluorescence techniques (Barton, 1966; Biswal *et al.*, 2003; Freeman *et al.*, 1978; Hurkman, 1979; Sundqvist and Dahlin, 1997; Suzuki *et al.*, 1997). One of the earliest changes is the disappearance of stacked grana regions followed by the elongation of lamellae. This distension is followed by massive degradation with a concomitant increase in the number and size of lipid droplets called plastoglobules and a swelling of the intrathylakoid space (Baker, 1992; Biswal, 1995; Biswal and Biswal, 1984; Matile *et al.*, 1999; Roberts *et al.*, 2003).

Recently, it was shown that chloroplasts remain outside of the vacuole, even at late stages of senescence, while the thylakoid membranes are internally dismantled. As thylakoids were dismantled, Rubisco large subunit protein (Lhcb1) and chloroplast DNA levels declined, but variable levels of mRNA persisted. This observation demonstrates that even though certain plastid components are degraded in the vacuole, the whole chloroplast was not transported into the vacuole for degradation, as suggested in previous studies (Evans *et al.*, 2009; Minamikawa *et al.*, 2001; Wittenbach *et al.*, 1982).

1.2.1. Control of chlorophyll catabolism

During autumn, it is common to see beautifully colored leaves. This is a result of the action of the catabolic pathway of chlorophyll (Chl), combined with the partial retention of carotenoids, and the accumulation and unmasking of colorless breakdown products with newly synthesized red anthocyanins and dark-colored oxidation products of phenolic compounds. Nevertheless, some authors propose that the removal of greenness in leaves has been underestimated, even though it is catalogued as the simplest and most easily measured index of leaf senescence syndrome (Thomas, 1997). Evidence indicates that the physiological pathway of yellowing is a robust and consistent component of the senescence syndrome and justifies its study in isolated organs and tissues in the plant (Ougham *et al.*, 2008). Chlorophyll degradation is a symptom of the transition of chloroplasts to gerontoplasts. A gerontoplast is defined as a distinctive senescence-specific form of plastids and is entirely catabolic. Developing gerontoplasts persist and remain intact throughout leaf senescence (Baker, 1992; Parthier, 1988). As leaf senescence proceeds, chlorophyll (Chl) levels decrease and photochemical efficiency of photosystem II and Rubisco protein levels decline (Evans *et al.*, 2009). Pathogen attack, as well as other biotic or abiotic stresses, can also accelerate premature leaf senescence and color change. Nevertheless, this pathological degreening has only a superficial resemblance to true senescence, proposed by some authors as “pseudo-senescence”. According to these authors, pseudo-senescence differs from the senescence in its genetic and biochemical components. Furthermore, it seems that senescence maintains viability in tissues that would otherwise rapidly divert into the pseudosenescence pathway and, therefore, avoid premature cell death (Ougham *et al.*, 2008).

The catabolic pathway of chlorophyll (Chl) during senescence and fruit ripening leads to the accumulation of colorless breakdown products so called non-fluorescent chlorophyll catabolites (NCCs) (Hörtensteiner, 2006). During catabolism, chlorophyll follows a route that initiates when chlorophyll is separated from the binding proteins within the thylakoid membranes (Ougham *et al.*, 2008). In the first proposed pathway, the chlorophyllase enzyme (Chlase) hydrolyses the ester linkage of the phytol chain to the porphyrin macrocycle of chlorophyll (Jacob-Wilk *et al.*, 1999; Matile *et al.*, 1999; Tsuchiya *et al.*, 1999), releasing phytol and chlorophyllide. In a second step, magnesium dechelatease removes the Mg^{2+} ion from the tetrapyrrole, converting chlorophyllide to the chlorin molecule pheophorbide (Pheide a) (Shioi *et al.*, 1996). Chlorophyll and its immediate catabolites are colored and strongly excited by ambient light. Thus, the catabolic route is organized in a way to avoid photodynamic damage by free pigments. The opening of the tetrapyrrole ring is a two-stage reaction which is catalyzed by PaO (Pheophorbide a oxygenase) and adds oxygen across the methine bridge between rings A and B (Hörtensteiner, 2006). A metal chelating substance (MCS) has been shown to be required for the activity of magnesium dechelatease (Tadashi, 2005). This pathway avoids the risk of photodamage, and the green color disappears when PaO opens the macrocycle of Pheide a (Rodoni *et al.*, 1997) and the red chlorophyll catabolite (RCC), a photoactive red pigment, appears (Ougham *et al.*, 2008). Immediately after this reaction, the RCC reductase abolished the photodynamic properties of RCC, resulting in the production of the colorless fluorescent Chl catabolite (pFCC) (Ougham *et al.*, 2008; Schenk *et al.*, 2007). The colorless linear product is exported from the plastid and in different ways depending on the plant species, may conjugate in the cytosol before being transported into the cell vacuole where the final chemical modification may take place (Hörtensteiner, 2006; Kräutler and Hörtensteiner, 2006; Tanaka and Tanaka, 2006). However, evidence inconsistent with this model has been presented by other authors. *AtCLH1* and *AtCLH2* are the only two Chlase genes reported in *Arabidopsis*, and it has been shown that (i) neither of these isoforms is localized to plastids, (ii) double knockout mutant plants are still able to degrade chlorophyll during leaf senescence (Schenk *et al.*, 2007), (iii) their activity could be detected prior to the onset of senescence (Benedetti and Arruda, 2002), and (iv) increases in Chl synthesis are also accompanied by increases in Chlase activity (Roca and Mínguez-Mosquera, 2003). This inconsistency generated an alternative description of the pathway during senescence. This model postulates that the removal of Mg^{2+} to form pheophytin occurs first and is followed by the removal of the phytol tail, catalyzed by pheophytinase (PPH) without a direct interaction with chlorophyll. This perspective generated the idea that chlorophyll synthesis and breakdown are metabolically separated during leaf senescence, and a careful revision of proposed pathway, as well as new experiments, are suggested to clarify the pathway of chlorophyll degradation during leaf senescence (Eckardt, 2009).

As a final step, the nonfluorescent chlorophyll catabolites (NCCs) produced during the opening of Chl macrocycles are deposited into the vacuole with any recycling of the nitrogen contained within them (Hinder *et al.*, 1996; Tommasini *et al.*, 1998). This presupposes that

degradation is required in principle to facilitate access to more valuable materials present in thylakoid proteins and lipids and to detoxify the cell of these highly reactive compounds, maintaining the viability of the cell during the process and not a nutrient salvage (Buchanan-Wollaston *et al.*, 2003; Matile *et al.*, 1999).

1.2.2. Chloroplast protein loss

Protein metabolism guarantees normal development and homeostasis in a plant cell. This complex process involves a broad spectrum of enzymes and manifold proteolytic pathways localized in different subcellular compartments (Grudkowska and Zagdanska, 2004; Vierstra 1996). Nitrogen exists mainly in chlorophyll and proteins. More than 75% of leaf protein is located within the chloroplast (Feller *et al.*, 2008a). Rubisco is the most abundant protein on earth and contributes up to 50% of the soluble proteins and up to 30% of total leaf nitrogen in leaves of C3 plants (Ellis, 1979; Feller *et al.*, 2008b). Some plant species are able to complete a life-cycle based on the initial supply of nitrogen during young developmental stages and eventually achieve good seed production. The most fundamental process in N-reabsorption is degradation of proteins, and its efficiency is close to 90%, thus being one of the most efficient of all metabolic pathways (Himmelblau and Amasino, 2001; Mei and Thimann, 1984).

Many genes involved in protein turnover, such as proteases (e.g. cysteine and aspartic proteases) (Woo *et al.*, 2004) and protein kinases, are significantly upregulated during senescence (Buchanan-Wollaston *et al.*, 2005). All of the amino acids derived from protein catabolism during senescence may be redistributed within the plant via the phloem and serve as basis/raw materials for protein synthesis in other organs of the plant. During senescence, a preferential expression of a specific set of “senescence-associated genes” (SAGs) has been reported, and based on the functional classes involved, there are three principal pathways that might regulate protein degradation: the ubiquitin/proteasome system; the chloroplast degradation pathway; and the vacuolar and autophagic (APG) pathway (Liu *et al.*, 2008).

In the ubiquitin/proteasome pathway, the covalent attachment of the 76-amino acid protein ubiquitin is used as a signal to target specific proteins for degradation by the 26S proteasome (Smalle and Vierstra, 2004). The principal enzymes involved are an ubiquitin-activating enzyme (E1), ubiquitin-conjugating enzyme (E2), and ubiquitin protein ligase (E3). Expression profile analysis during leaf senescence in *Arabidopsis* revealed a large number of genes of the ubiquitin-26S proteasome pathway, suggesting that ubiquitin-dependent proteolysis might be an important step in protein degradation outside the chloroplast (Park *et al.*, 1998). It has been shown that *UBQ3* and *UBQ4* are the predominant polyubiquitin genes up regulated, while other ubiquitin-related protein genes are also highly represented (Lin and Wu, 2004).

Proteolysis of chloroplast proteins (Chlp) takes place during the transition from proplastid to plastid, or during senescence (Adam, 1996). Proteases localized to the stroma, the

thylakoid membrane, and the thylakoid lumen have been described (Adam *et al.*, 2001). The *Arabidopsis* genome contains at least 23 genes predicted to encode Chlp proteases located in the stroma, and most of them have been described during leaf senescence (Adam *et al.*, 2001; Adam and Clarke, 2002; Gottesman, 1996; Liu *et al.*, 2008; Sakamoto, 2006). Nevertheless, degradation of the light-harvesting complex of Photosystem II (LHCII) is still poorly characterized, and the protease/proteases involved, as well as their exact role, remain to be uncovered (Liu *et al.*, 2008).

The autophagy (APG) pathway is a catabolic process that allows recycling of cytoplasmic components (including organelles) into monomers and is the last proposed pathway of protein degradation. Through this pathway, protein degradation occurs via micro or macroautophagy. In microautophagy, targeted cytosolic components are enclosed in lysosomal or vacuolar membranes via invagination (Klionsky and Ohsumi, 1999; Mukaiyama *et al.*, 2002). By contrast, macroautophagy takes place in the cytoplasm and is initiated with the generation of membranes that can eventually fuse and form autophagosomes in which enclosed material can be transported into the vacuoles and degraded by vacuolar exo- and endoproteases, such as cysteine proteinase (*SAG12*), aspartic proteinase, serine proteinase, and other peptidases which are well documented during leaf senescence (Buchanan-Wollaston, *et al.*, 2003; Buchanan-Wollaston, *et al.*, 2005; Klionsky and Ohsumi, 1999; Lin and Wu, 2004). Recently, it has been reported that autophagosome formation requires essentially two ubiquitin-like proteins, ATG8 and ATG12, which conjugate with phosphatidylethanolamine (PE) and ATG5, respectively, forming ATG8-PE and ATG12-ATG5 complexes in higher eukaryotes (Geng and Klionsky, 2008). Other studies in wheat, soybean, tobacco, and *Arabidopsis* revealed the presences of vesicles in the cytoplasm that include Rubisco and/or Rubisco degradation products and other stromal proteins, and also small senescence-associated vacuoles involved in the degradation of chloroplast proteins (Chiba *et al.*, 2003; Martínez *et al.*, 2008).

1.2.3. Degradation of membrane components and lipid breakdown

In plants, like in other eukaryotes, lipids are used for membrane biogenesis, in molecular signaling, as a source of energy, and as a protective layer that does not permit desiccation and infection. The chloroplast and other organelles present in plant cells have the capacity to synthesize fatty acids and confer to plants not only a different lipid composition, but also a different metabolic pathway when compared to animal cells. Contrary to animal lipid bilayers, chloroplast and other plastids are largely composed of galactolipids, rather than phospholipids, as the predominant lipids in green tissues. The thylakoid membrane system is mainly composed of phosphatidylglycerols, whereas most of the limited phosphatidylcholine in chloroplasts is associated with their outer membrane (Cullis *et al.*, 1996). These fatty acids cannot be transported for long distances in the plant; due to this, the only way to use them as a practical carbon reserve for growing tissues is through the conversion of acetyl-CoA to sucrose by beta-oxidation. The content of fatty acids in green leaves represents

around 5% of their dry weight and 10% of the total energy (Nishimura *et al.*, 1993; Schmid and Ohlrogge, 2002).

It has been reported that the levels of monogalactosyl diglyceride, digalactosyl diglyceride, and phospholipid phosphatidylglycerol decline at the onset of leaf senescence accompanied by a progressive decrease as senescence advances. In contrast, waxes present in *Arabidopsis* leaves exhibited only a minor reduction during senescence (Ferguson and Simon, 1973; Fong and Heath, 1977; Harwood *et al.*, 1982; Koiwai *et al.*, 1981; Wanner *et al.*, 1991; Yamauchi *et al.*, 1986). Active metabolism of fatty acids is a typical feature of seed germination and seedling growth. In addition, the process is also necessary during senescence to guarantee the flux of stored carbon from leaves to other developing organs like seeds, and to eliminate negative effects of free fatty acids after the hydrolysis of lipids (Graham, 2008). Membrane disruption has been proposed to be a key event in plant senescence. One of the most characteristic features in membrane deterioration is a progressive decline of phospholipid levels with a relative enrichment of free fatty acids and sterols in the membranes, accompanied by an increase in the level of different enzymes (McKersie and Thompson, 1978; Thompson *et al.*, 1982).

It is well documented that leaf peroxisomes are transformed directly to glyoxysomes during senescence (Nishimura *et al.*, 1993). The peroxisome of senescent leaves metabolize the fatty acids after hydrolysis by the β -oxidation pathway (Gerhardt, 1992). Lipid-degrading enzymes, such as phospholipase D (PLD), phosphatidic acid phosphatase, lipolytic acyl hydrolase, and lipoxygenase, constitute the first degradation machinery of membrane phospholipids (Thompson *et al.*, 1998). Some of the products from lipid catabolism may serve as substrates for other reactions; this is the case for free linoleic acid that is released during membrane lipid degradation and later used for jasmonic acid biosynthesis (Creelman and Mullet, 1997).

When lipid-degrading enzymes degrade membrane phospholipids and release free fatty acids, the bilayer structure of the membrane is perturbed. This facilitates the action of other lipid-degrading enzymes like SAG101 acyl hydrolase, which was proposed to be one of the key enzymes during the onset of leaf senescence (Thompson *et al.*, 1998; Yang and Ohlrogge, 2009). In addition, some authors have suggested an additional nonenzymatic oxidation pathway that includes an autoxidation due to reactive oxygen species, such as superoxide anion, hydrogen peroxide, and hydroxyl radical (Fong and Heath, 1977; Paliyath and Droillard, 1992; Thompson *et al.*, 1998). Finally, plants can use the fatty acids from this step of lipid degradation to obtain energy by oxidation of the fatty acids. The glyoxylate cycle produces succinate and malate. These are converted to oxaloacetate, which then enters into the gluconeogenesis pathway to produce sugars and, ultimately, sucrose. This final product can then be transported by the phloem to other plant organs (Buchanan-Wollaston, 1997; Smart, 1994).

1.3. Integration of hormonal changes during leaf senescence

Senescence of different organs in the plant can be regulated by external and internal factors. Internal factors influencing senescence include the developmental stage as well as endogenous levels of phytohormones and other growth substances. These factors may act individually or in concert (He *et al.*, 2001). In general phytohormones are able to promote or repress the senescence process. Cytokinin, auxin, gibberellic acid (GA), and polyamines are considered to delay senescence, whereas ethylene, abscisic acid (ABA), jasmonic acid (JA) and its derivative methyl jasmonate (MeJA), salicylic acid (SA), and brassinosteroids (BRs) are thought to be involved in its induction. Published data show an overlap between different hormone signaling pathways during normal plant development and in response to different abiotic and biotic stresses, making the study a real complex task (Lim *et al.*, 2001). Research on phytohormones and their influence on plant senescence is normally based on the external application of the hormone, the measurement of endogenous levels before and after the onset of senescence, and finally, molecular analysis in which modification of the phytohormone levels in specific organs is measured in mutants or transgenic lines. A vast amount of documentation is available on the effects of plant hormones during senescence. In the following, I present a brief overview of the documentation and try to highlight important findings regarding hormonal effects on senescence.

1.3.1. Hormones promoting senescence

A correlation between ethylene production and leaf senescence has been reported in several plant species. An increase in the level of ethylene promotes senescence and some of its specific components, such as the degradation of chlorophyll, proteins, and other macromolecules, a rise in the expression of different senescence associated genes (SAGs), and the enhancement of catabolic enzyme activities (Mattoo and Aharoni, 1988). Molecular analysis of the ethylene perception and signal transduction mutants *etr1* and *ein2* revealed an increase of the lifespan as a consequence of a delay in the onset of senescence (Aeong Oh *et al.*, 1997; Grbic and Bleeker, 1995). Nevertheless, some authors have pointed out that ethylene, itself, is neither necessary nor sufficient for promoting leaf senescence in some species such as *Arabidopsis*. Furthermore, this hormone may promote senescence only in mature or old leaves, and in comparison to floral organs or fruits, its effect on leaves is considerably less pronounced (Grbic and Bleeker, 1995).

The second plant hormone responsible for the promotion of senescence is JA. Some studies of wild type *Arabidopsis* plants revealed that the exogenous application of this phytohormone might induce premature senescence in attached and detached leaves, but its exogenous application to mutant *coil* plants could not induce premature senescence, suggesting the importance of the complete signaling pathway to promote leaf senescence (He *et al.*, 2002). Transcriptional analysis revealed an upregulation of genes involved in JA biosynthesis during

leaf senescence; but even when plants underproduce JA (in the case of JA mutants), there is no significant retardation in leaf senescence, and this hormone pathway probably plays just a secondary role or complements other signaling pathways during senescence (Gan and Amasino, 1997; Harms *et al.*, 1995).

SA is another hormone involved in plant senescence. Its role in the process has recently been documented. SA plays a role in the initiation of senescence and may share the same pathway as stress responsive genes. The endogenous levels of SA increase in parallel with the progression of senescence, and *Arabidopsis* plants with a deficiency of SA exhibit a retardation of senescence and changes in SAG expression (Abreu and Munné-Bosch, 2008; Morris *et al.*, 2000).

The last two plant hormones involved in the promotion of senescence are brassinosteroids (BRs) and abscisic acid (ABA). Despite evidence for a positive influence on the progression of senescence, their specific roles are still unclear. In the case of BRs, there is evidence for the induction of senescence by external application of 24-epibrassinolide (eBR). Furthermore, *Arabidopsis* mutants which lack BR, such as *det2* or *bri1*, show a leaf senescence phenotype (Bishop and Koncz, 2002; Clouse, 1997; Clouse *et al.*, 1996). In addition, reactive oxygen species (ROS) signaling may have links with the BR signaling pathway, and through this, may mediate BR-induced senescence.

1.3.2. Hormones delaying senescence

Cytokinins have the strongest effect on the longevity of plant organs, and their impact in delaying senescence is one of the most documented topics in plant physiology (McCabe *et al.*, 2001; Richmond and Lang, 1957). Modifications in cytokinin biosynthesis allowed detection of a delay of senescence in different plant organs and a significant increase in plant productivity (Gan and Amasino, 1995; Nelson, 1988), whereas reduction of the endogenous levels resulted in an acceleration of the process (Masferrer *et al.*, 2002). There is an inverse correlation between the endogenous cytokinin levels and senescence progression. Mutants carrying defects in the cytokinin biosynthesis pathway gave strong evidence of its effect in the retardation of senescence (Gan and Amasino, 1996). Due to the fact that cytokinins are implicated in a wide range of physiological processes in plants and are often influenced by developmental processes of other organs/tissues, the effect of this phytohormone depends on several external and internal factors and varies under different experimental conditions (Gan and Amasino, 1995; Gan and Amasino, 1996).

Auxins are the second group of plant hormones involved in the retardation of senescence; external application of the hormone delays senescence, and a negative correlation exists between the endogenous auxin levels and the degree of leaf senescence. Some of the

senescence features, like chlorophyll loss and protein degradation, were established by the application of either synthetic or natural auxins (Noodén and Leopold, 1988). A more recent study finds that overexpression of the *Arabidopsis thaliana* *YUCCA6* gene, which encodes a member of the flavin monooxygenase protein family that limits de novo auxin biosynthesis, exhibits the classic delayed, dark-induced and hormone-induced senescence in detached rosette leaves, as showed the mutant (Kim *et al.*, 2011).

The effects of gibberellins on natural senescence, and their relationship with senescence, are not fully understood. Experimental data suggested that GAs are able to inhibit mitotic and postmitotic senescence in pea apical buds (Zhu and Davies, 1997), and postmitotic leaf senescence in many other plant species. The mitotic, or proliferative senescence is defined when germline-like meristem cells lose their ability to undergo mitotic cell division. In contrast, the postmitotic senescence refers to an active degenerative process that occurs in organs such as leaves and floral petals (Gan, 2003). The increase in GAs by external application inhibits the degradation of chlorophyll, proteins, and/or nucleic acids in leaves (Noodén and Leopold, 1988). Among different kinds of gibberellins, GA4 has a strong effect in delaying leaf senescence in different species (Gan, 2010; Kappers *et al.*, 1998; Ranwala and Miller, 2000). Like other groups of hormones, the effect of GAs is highly dependant on many internal and external factors as well as the species being used for the study.

1.4. Abiotic and biotic stresses

Leaf longevity and abiotic stress are closely related terms, and strong evidence supports the model that both physiological plant traits are regulated by a partially overlapping set of complex molecular networks (Buchanan-Wollaston *et al.*, 2005; Breeze *et al.*, 2011). Stress is generally understood as the reaction of a biological system to extreme environmental factors that, depending on intensity and duration, may cause significant changes in the system (Godbold, 1998; Orcutt and Hale, 2000). Favorable or disadvantageous factors press the plants throughout their entire life. Plants are sessile organisms and cannot move away from adverse environmental conditions or perturbations. To compensate for this deficiency, plants have developed a variety of molecular strategies against biotic and abiotic stresses. According to this idea, each organism displays a specific genetic tolerance to a specific stress. The definition of stress is present in the cases where external changes exceed this tolerance, and plants must not only change their metabolism but also lose the equilibrium. Thus, the normal energy consumption, growth, development, and productivity are affected and finally cause bodily injury, disease, or aberrant physiology (Gaspar *et al.*, 2002; Mandre, 2002). Those biotic stressors are concerned with the mechanism of interaction between different species like in the case of diseases and herbivores; these are of particular interest to forest and agricultural systems (Orcutt and Hale, 2000). Abiotic stressors may be of physical or chemical character and include stresses associated with temperature, salinity, and drought, and they may act alone or in combination. (Mandre, 2002; Orcutt and Hale, 2000).

Various gene expression-profiling studies revealed that many genes encoding NAC transcription factors are induced during both natural and abiotic stress-induced senescence (Buchanan-Wollaston, 1997; Olsen *et al.*, 2005; Uauy *et al.*, 2006; Yang *et al.*, 2001, 2003; Balazadeh *et al.*, 2008b). Therefore, the functional characterization of senescence-associated NAC transcription factors may provide important information with respect to understanding senescence-regulatory pathways and their overlap with stress-response signaling pathways.

1.5. Regulation of gene expression: the role of transcription factors

The development of any organism depends on proper coordination of gene expression. The genetic information encoded in the DNA must first be converted into mRNA through the action of RNA polymerase II in a process called transcription; subsequently, the produced transcript serves as a template for the generation of a specific protein through translation. RNA polymerase II cannot bind directly to promoters and initiate transcription itself. Therefore, one of the most important points in this mechanism is the regulation of gene transcription via transcription factors (TFs). TFs are a very broad category of DNA binding proteins with a positive (activation) or negative (repression) effect on transcription. The central role of transcription in the process of gene expression is exemplified by general transcription factors (GTFs), such as TFIIA, TFIIB, TFIID, TFIIE, TFIIIF, and TFIIH, present in eukaryotes. These are necessary not only for control in a large-scale regulation of different genes, but also for the initiation of transcription itself (Facciotti *et al.*, 2007). A key challenge in genetic research is to understand how TFs bind the correct DNA sequence to control gene expression. Transcription establishes a control point for regulating gene expression and gives the ability to perform different functions by generating alternative splicing of the same transcript. Several factors are required to locate and orient the RNA polymerase correctly, and each is given by different time-specific molecular events at the end the expression of a gene. In addition to the GTFs, recognition and response to regulatory signals requires promoter-regulatory sequences (*cis*-regulatory elements). The specific recognition of a *cis*-element is given by the conformation and three-dimensional structure of the TF, allowing its DNA to bind. A multiprotein complex called transcriptional mediator, or mediator complex, is required to transmit signals from transcription factors to the RNA polymerase II initiation complex (**Fig. 1**) (Latchman, 2008).

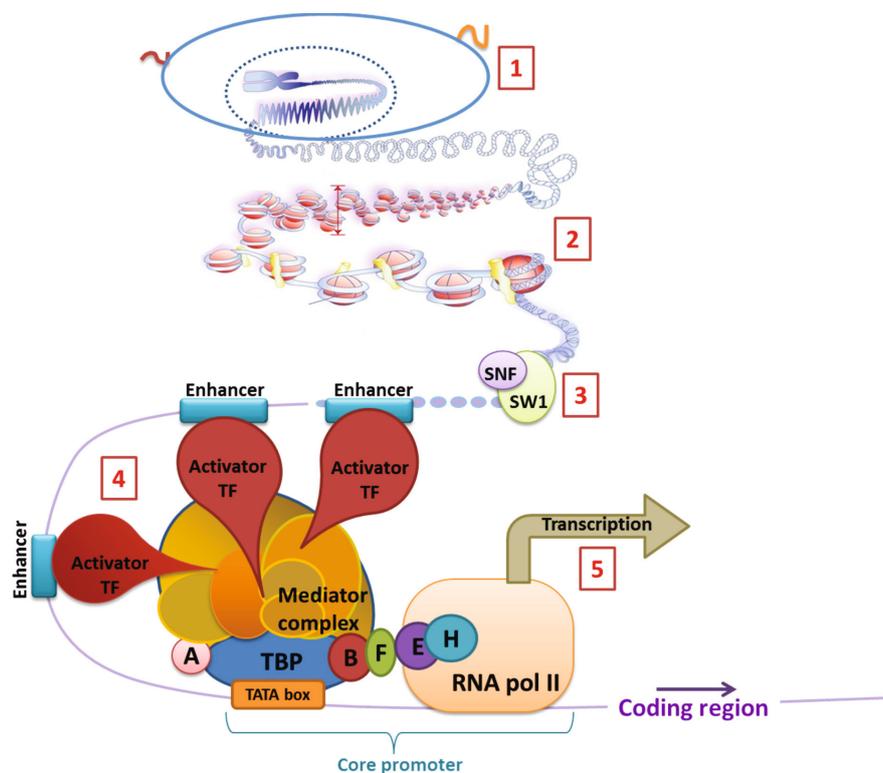

Figure 1. Schematic view of the molecular events in the expression of a gene. (1) Transduction of signals from the cell surface to the nucleus. (2) Beads on a string form of chromatin. (3) Nucleosome disassembly by SWI/SNF complexes and histone chaperones. (4) In combination with general transcription factors, RNA polymerase II forms the preinitiation complex (PIC). This complex is assembled at the core promoter region and is able to initiate transcription. The core promoter is the minimal promoter (approximately 34 bp up-stream of the start codon) which is required for transcription initiation. It is formed by TBP (TATA binding protein), some activators (as TF), and some coactivators. Those factors are required to transmit regulatory signals from transcription factors to the RNA pol II. In addition to promoters, other regulatory regions, such as enhancers, may be required for full expression. (5) Gene transcription by RNA polymerase II.

TF families are classified based on structural similarities. The PlnTFDB (Plant Transcription Factor Database) reports 2657 protein models and 2451 distinct protein sequences of *Arabidopsis thaliana* arranged in 81 gene families (Pérez-Rodríguez *et al.*, 2010). Classification of those TFs is given on the basis of sequence similarities, most often in the DNA-binding domain (DBD) (Guo *et al.*, 2005). Within families, the members are similar to each other only in their DNA-binding. The names of the DBDs (e.g., AP2/ERF or EREBP, WRKY, NAC) are also used as the names of the transcription factor families. Frequently, the same family binds DNA in a sequence-specific manner, and this region is highly conserved. In contrast, the transcription regulatory domain (TRD) has been classified according to its amino acid profile, i.e., as acidic, glutamine-, proline- or serine/threonine-rich, and exhibits protein segments that determine the three-dimensional structure of the TF with a relative flexibility (Luscombe and Thornton, 2002; Skriver *et al.*, 2010; Tompa, 2005). The NAC transcription factors, along with the MYB, AP2/EREBP,

and bHLH proteins, are the largest families of transcription factors in the plant kingdom (Riechmann *et al.*, 2000). The specificity of the DNA-binding activity could be modulated by the presence of more than one domain in a single TF as well as homodimerization or heterodimerization. Modifications like phosphorylation, glycosylation, nuclear transport, and oligomerization are important post-translation modifications that can control TF activity (Meshi and Iwabuchi, 1995).

1.5.1. Molecular regulation of senescence

Breakdown of different macromolecules, and their massive remobilization from senescent to young tissues, requires that cells retain their nuclear integrity to allow for effective transcription and further translation of proteins; thus nuclei remain intact until the very late stages of senescence. In the particular case of senescence, regulation of the process is reported to be strictly controlled by the molecular interaction of genes known as senescence associated genes (SAGs) and modulated by internal and environmental signals (Buchanan-Wollaston, 1997; Gan and Amasino, 1997). It is well known that its progression can be inhibited by enucleation and inhibitors of RNA and protein biosynthesis, and it is highly controlled by gene expression (Noodén and Leopold, 1988). There are more than 100 genes differentially up regulated during the process. Among them, NAC and WRKY TFs constitute a large proportion of the senescence-regulated genes already assigned to play an important role in *Arabidopsis* senescence (Balazadeh *et al.*, 2008a,b; Breeze *et al.*, 2011). Despite the importance of senescence, few SAGs have been completely characterized; some of them, like *SAG12* (encoding a cystein protease), *SAG13* (oxidoreductase), *SAG101* (acyl hydrolase) from *Arabidopsis* (He and Gan, 2002), and *LSC54* (a gene encoding methallothionein) from *Brassica napus* (Buchanan-Wollaston, 1994) are highly upregulated during the onset and progression of senescence. Nevertheless, their expression is not exclusive to the senescence process, and expression of *SAG12* and *SAG13* was also reported in floral organs. Other genes involved in the genetic control of senescence, like the *senescence-associated gene 1* (*SEN1*), are detectable during all stages of leaf development but show a significant increase in expression during senescence (Gan and Amasino, 1997).

1.5.2. The NAC transcription factor family

The NAC transcription factor family was first reported as the *RESPONSIVE TO DEHYDRATION 26* (*RD26*) gene in *Arabidopsis*. The name “NAC” has been derived from the first letters of the first three genes described as containing the NAC domain: (i) the petunia gene *NAM* (no apical meristem); (ii) *ATAF1/2*; and (iii) *CUC2* (cup-shaped cotyledon) from *Arabidopsis* (Miyoshi *et al.*, 2002; Nakashima *et al.*, 2007; Yamaguchi-Shinozaki *et al.*, 1992). NAC proteins appear to be widespread in plants. For example, the genome of *Arabidopsis thaliana* contains around 100 NAC-encoding genes, whereas NAC

genes appear to be absent from algae and other eukaryotes, indicating that the family has emerged from an event likely related to the water-to-land transition in plants along with the challenges that this transition may have imposed (*Arabidopsis*, 2000; Lang *et al.*, 2010; Ooka *et al.*, 2003; Riechemann *et al.*, 2000). NAC transcription factors are related to a variety of plant-specific processes, such as development of plant-specific organs (Aida *et al.*, 1997; Souer *et al.*, 1996), responses to plant hormones (Greve *et al.*, 2003; Xie *et al.*, 2000; Yang *et al.*, 2011), and responses to drought and high salinity stresses (Balazadeh *et al.*, 2008b; Balazadeh *et al.*, 2010a,b; Seki *et al.*, 2002; Yamasaki *et al.*, 2008). Analysis of conserved amino acid residues and construction of a phylogeny with the conserved NAC domain in *Arabidopsis*, rice, lycophyte (*Selaginella moellendorffii*), and moss (*Physcomitrella patens*) gave strong support for an early appearance of NACs in an ancient plant lineage, which probably emerged after the separation of lycophytes and other vascular plants prior to the separation of monocots from dicots (Nakashima *et al.*, 2011). Crystallography and global transcriptional analysis not only revealed a structural similarity, but also demonstrated that the NAC domain lacks a classical helix–turn–helix motif, and it possesses a new type of TF-fold consisting of a twisted beta-sheet that is surrounded by a few helical elements (Olsen *et al.*, 2005b).

The typical NAC domain (DNA-binding domain) is located in the N-terminal region and is divided into five conserved regions, or subdomains (A to E), containing around 150 amino acids (Ooka *et al.*, 2003; Yamasaki *et al.*, 2008). This domain also contains a nuclear localization signal. In contrast, the variable C-terminal region contains a transactivation domain and exhibits protein-binding activity (Seo *et al.*, 2008; Tran *et al.*, 2010; Yamasaki *et al.*, 2008) (**Fig. 2.A**). Additionally, some NACs from *Arabidopsis* and rice have been shown to contain α -helical transmembrane motifs in the terminal part of the C-terminal region. These motifs help the proteins anchor to intracellular membranes, and at the same time, make them inactive; only through controlled proteolytic cleavage from this anchor can the proteins recover their activity and exert their functions (Kim *et al.*, 2007). Even though NAC proteins share a common structure, recent studies revealed few atypical NAC genes that show variations from the usual structure. Some encoded only the NAC domains, while others exhibit a C-terminal NAC domain with variable regions in the terminal part of the N-terminal region (Christiansen *et al.*, 2011; Ooka *et al.*, 2003) (**Fig. 2.B**).

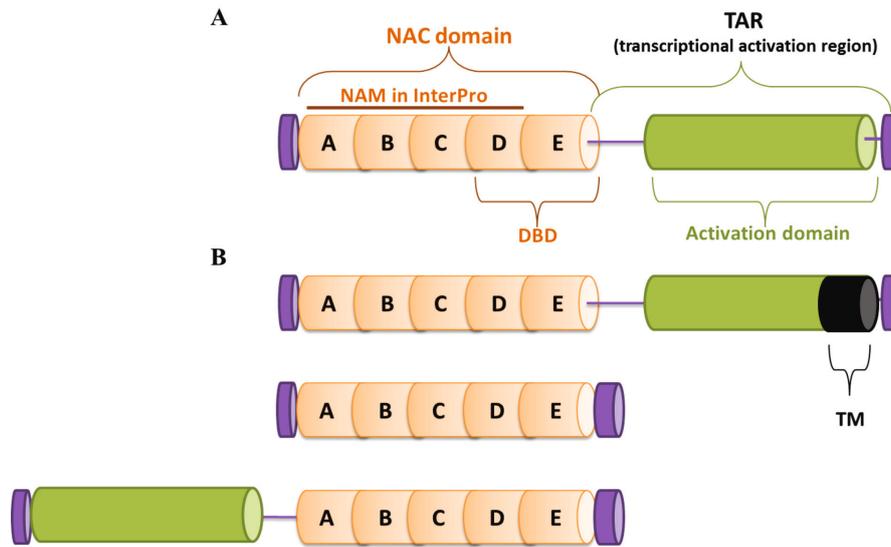

Figure 2. Structural characteristic of NAC proteins. (A) The highly conserved NAC domain is located at the N-terminal region and consists of five sub domains (A to E). The C-terminal region includes a highly divergent transcriptional activation region. (B) Structural modifications of the typical NAC protein. Some NAC proteins exhibit transmembrane domains (TM) in the C-terminal region. Other NACs encode only the NAC domain or have the NAC domain in the C-terminal region. Modified from (Christiansen *et al.*, 2011; Ooka *et al.*, 2003).

The molecular characterization of NAC proteins began with the report of two NAC proteins that were able to activate the Cauliflower Mosaic Virus (CaMV) 35S promoter in yeast (Souer *et al.*, 1996), and it was followed by the characterization of *NAC1*, *AtNAM* and *ANAC019* in *Arabidopsis*, and others in *Brassica napus* (Duval *et al.*, 2002; Ernst *et al.*, 2004; Hegedus *et al.*, 2003; Xie *et al.*, 2000). Later, the core sequence (CACG) was identified as the DNA motif recognized by the ANAC proteins *ANAC019*, *ANAC055*, and *ANAC072* that allows their binding to a fragment of the *ERD1* (*EARLY RESPONSE TO DEHYDRATION STRESS 1*) promoter (Tran *et al.*, 2004). One year later, the consensus binding sequences of three members of the NAC family were determined by two different methods. The DNA protein binding (DPB)-CeLD-fusion method was used to identify the consensus sequence of the wheat TF *TaNAC69*, a homologue of *AtNAP* from *Arabidopsis* (Xue, 2005), and the CASTing (cyclic amplification and selection of targets) method allowed the identification of the core binding sequence (CGT(G/A)) of *ANAC019* and *ANAC092* (Olsen *et al.*, 2005a). After determining the core sequence, electrophoretic mobility gel shift assays (EMSAs) confirmed that NAC domains are able to bind to a sequence containing one identified binding site (CGTG) and a sequence containing two identified binding sites in a palindromic orientation (TTGCGTGTTNNCACGCAA) (Olsen *et al.*, 2005a). One of the most recently characterized NAC genes is *ORS1*, a paralog of *ANAC092* that positively regulates senescence through a regulatory network that might be involved in the cross-talk between salt and H₂O₂-dependent signaling pathways. Determination of its consensus binding sequence was reported and analyzed among *ORS1* down-stream genes (Balazadeh *et al.*, 2011).

The large number of biological processes regulated by NAC TFs in plants not only highlights their general importance in plant biology, but also indicates that its functional characterization will provide valuable information about the initial inputs and final outputs through which plants regulate the senescence syndrome.

1.6. Aim of the thesis

Leaf senescence is a complex developmental process that delimits the lifespan of one of the most important organs responsible for photosynthesis in plants. During senescence, leaves undergo a massive degradation process that affects all of their physiological traits including their photosynthetic capability. Leaf senescence requires a tight control that ensures the synchronous dismantling of the cellular components, relocation of the degraded products, and maintenance of the nucleus integrity in the leaf until the very end. Primarily, senescence regulatory genes and their signaling networks must be fully characterized to understand senescence as an integrative process. The progress in the plant senescence field must later be extended to practical approaches to improve food longevity and decrease food losses in all stages of the crop postharvest system, as well as to understand the environmental factors that cause precocious senescence, which makes plants more susceptible to diseases and plagues.

My contribution to this ambitious idea is contained in the main objective of my thesis: unravel the signaling cascade through which *ORE1*, a key regulator of leaf senescence, exerts its function. To this end, I analyzed particular features of *ORE1* up-stream and down-stream regulatory pathways.

Chapter 2

Unraveling the up-stream regulatory pathway of *ORE1*

Part of this work was published in *The Plant Journal* (2010), 62, 250-264.

“A gene regulatory network controlled by the NAC transcription factor ANAC092/AtNAC2/ORE1 during salt-promoted senescence”

2.1. Introduction

The plant transcription factor *ORE1* (At5g39610) has been reported to play a key role in natural and induced senescence in *Arabidopsis* (Kim *et al.*, 2009; Balazadeh *et al.*, 2010a,b; Breeze *et al.*, 2011). A general approach to unravel transcriptional regulatory pathways includes the analysis of the up-stream signaling pathways that control the expression of the respective gene. Besides others, this involves the identification of *cis*-regulatory elements (CREs) present in the promoters of the genes under analysis and, subsequently, the search for TFs that bind to them. Currently, CREs of the *ORE1* promoters are poorly characterized. There are only one up-stream regulator of *ORE1* described thus far: *miR164*. This regulation corresponds to a trifurcate feed-forward regulation that involves *EIN2*, *miR164*, and *ORE1* (Kim *et al.*, 2009). *EIN2* is a membrane-spanning protein whose biochemical functions are still unknown, but genetic studies indicate that it is absolutely required for ethylene signaling (Alonso *et al.*, 1999; Kim *et al.*, 2009). It has been shown that *ORE1* expression increases in an age-dependent manner, apparently through induction by *EIN2*. *miR164*

targets *ORE1* and down-regulates its expression. However, expression of *miR164* decreases with age through an unknown mechanism. This complex regulatory mechanism suggests that *ORE1* expression is tightly regulated to avoid up-regulation in young leaves that lead to premature senescence and cell-death (Kim *et al.*, 2009). The MADS-box transcription factor *SEPALLATA3* (*SEP3*) was characterized based on a genome-wide DNA-binding profile and targets *ORE1*. Chromatin immunoprecipitation (ChIP), followed by ultrahigh-throughput Solexa sequencing (ChIP-seq), were used to obtain direct target genes of *SEP3* and construct a framework for a hierarchical transcriptional network underlying the formation of floral organs. Interestingly, the study determined that *SEP3* binds *in vivo* to the *ORE1* promoter. Nevertheless, the biological relevance of this interaction remains unknown (Kaufmann *et al.*, 2009). Understanding how the expression of *ORE1* is modulated is essential to reconstruct its regulatory network and provide information on the molecular mechanisms that control senescence in *Arabidopsis*.

2.2. Results

2.2.1. Tissue-specific expression of *ORE1* is conserved in *Arabidopsis thaliana* and *Nicotiana tabacum*

Reporter genes were used to investigate the tissue-specific expression of *ORE1* transgenic lines harboring a 1.5 kb sequence up-stream of the start codon ATG fused to the *Staphylococcus β-glucuronidase* (*GUS*). *Prom1-ORE1:GUS* constructs were transformed into *A. thaliana* ecotype Col-0 and *N. tabacum* L. cv. Samsun plants. Independent transgenic lines of the T4 and T5 generations were used to assess the *GUS* activity mediated by the *ORE1* promoter. We identified conserved expression patterns in both species among different organs and tissues. Representative expression patterns are shown in **Figure 3**. In both species, the expression of *GUS* was observed in most tissues from early stages right after germination to the end of the plant's life cycle. Strong and rapidly appearing *GUS* activity was observed in mature embryos extracted from seeds (detected already after 30 minutes of staining) and in cotyledons (**Fig. 3. Panel A.a-f**). Embryos were extracted after imbibition in water for 10 hours to avoid damage of the tissues while removing the testa. The expression of the *ORE1* promoter in cotyledons and in the tip and margin regions of the leaves in young seedlings (15-day-old) was in accordance with reported progression of aging from the tip to the base of the leaves (**Fig. 3. Panel B.a-b**) (Hill, 1980). In primary roots, we observed *ORE1* promoter-driven *GUS* staining particularly in the columella root cap (**Fig. 3. Panel B.c-d**). *GUS* activity was absent in young leaves (data not shown). In contrast, older leaf parts exhibited the same expression patterns detected on seedling leaves (tip and margin regions) when senescence became apparent. *GUS* staining was evident in response to mechanical damage in mature leaves in both species (**Fig. 3. Panel C and D.c-d**). Expression was also detected in floral organs, especially in sepal and petal tips and mature anthers in *Arabidopsis* and tobacco. Strong *GUS* activity was detected in

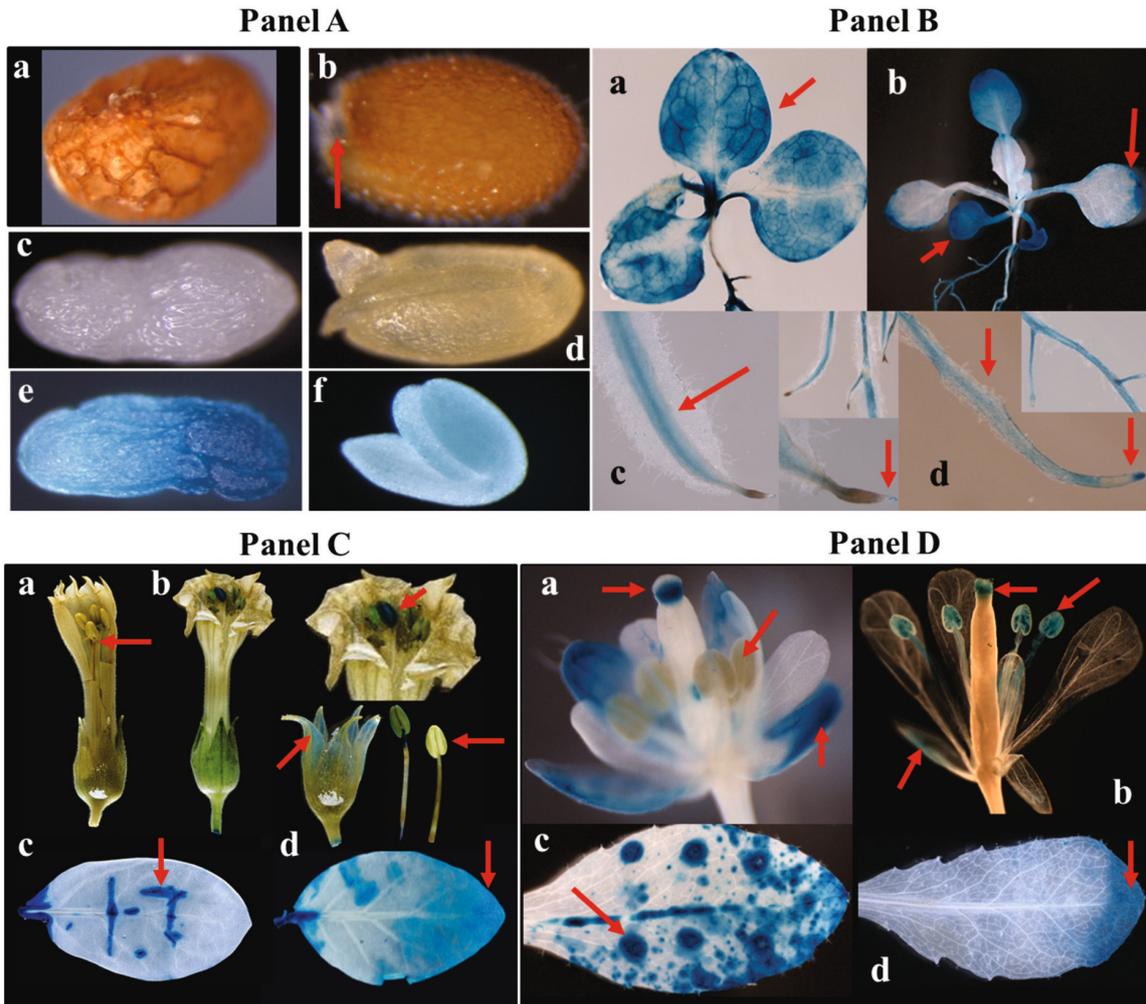

Figure 3. ORE1 driven GUS expression in tobacco and *Arabidopsis*. **Panel A.** (a) Tobacco and (b) *Arabidopsis* seeds with testa. Faint GUS staining was detected near to the testa rupture site in *Arabidopsis* (indicated by arrow). (c-d) Tobacco and *Arabidopsis* mature embryos without testa before GUS staining, respectively. (e-f) The same embryos after GUS staining (30 minutes). **Panel B.** (Upper corner right). (a) Tobacco seedling (15-day-old) after 12 hours GUS staining. (b) *Arabidopsis* seedling (15-day-old) after one hour GUS staining. Strong GUS activity was detected in both species in cotyledons and the tip regions of leaves in *Arabidopsis* (indicated by arrows). (c) Tobacco and (d) *Arabidopsis* main roots from seedlings (15-day-old). Strong GUS staining in the columella root cap and among the roots covering the elongation zone (indicated by arrows). **Panel C.** (Lower corner left) (a) Young tobacco flower. Promoter GUS expression was absent in immature anthers and was weak in the stigma papillae and tip region of the sepals (indicated by arrows). (b) Mature tobacco flower exhibited strong promoter GUS activity in mature anthers and faint activity in sepal tips (indicated by arrows). (c-d) Mature leaves from tobacco showed strong GUS activity in the tip of the leaves and also in response to mechanical damage. **Panel D.** (Lower corner right) (a) *Arabidopsis* unfertilized flower at stage 12 of development into mature plant (28-day-old) showing strong GUS activity in tips of sepals and in upper part of stigma corresponding to the stigmatic papillae. GUS activity was absent in immature anthers (indicated by arrow, flower was opened for picture). (b) Open flower from mature *Arabidopsis* at stage 15 of development exhibiting strong GUS activity in mature anthers and faint activity in tip region of sepals. (c-d) *Arabidopsis* leaves from mature plant (40-day-old). GUS promoter activity detected in response to mechanical damage (left) and in tip region of the leaves corresponding to oldest tissue (right).

the stigma at the stigmatic papillae in unfertilized *Arabidopsis* young flowers at stage 12 of floral development. This was when the stigmatic papillae was visible, the petals reach the height of the medial stamens, and anthesis had not yet taken place (Smyth *et al.*, 1990). In a mature plant at stage 15 (28 days old), strong GUS activity was also detected in the stigmatic papillae of mature stigma in the opened mature flowers when stigma extended above the long anthers (Ferrándiz *et al.*, 1999). Immature anthers and petals did not show any GUS activity in *Arabidopsis* or tobacco (**Fig. 3. Panel C-D.a**). Expression was also detected in floral organs, especially in sepal tips and mature anthers in *Arabidopsis* and tobacco.

2.2.2. *ORE1* controls dark-induced senescence in *Arabidopsis*

It is well established that senescence can be triggered and enhanced by endogenous and exogenous factors (Bleecker, 1998; Buchanan-Wollaston *et al.*, 2005; Gan and Amasino, 1997; Gepstein *et al.*, 2003; Howard *et al.*, 2009; Weaver and Amasino, 2001). Despite the relevance of light as an exogenous factor involved in both senescence inhibition and promotion, the regulatory pathways involved in those processes are not well understood (Biswal and Biswal, 1984; Noodén and Guimét, 1996; Weaver and Amasino, 2001). Based on published studies, the absence of light is more commonly considered an inducer of senescence. The artificial induction of senescence has been reported in detached leaves placed for several days in the dark (Weaver and Amasino, 2001). Several genes associated with dark-induced senescence have been identified in *Arabidopsis* (Blank and McKeon 1991; Kleber-Janke and Krupinska 1997; Buchanan-Wollaston *et al.*, 2005; Van Der Graaff *et al.*, 2006). To test whether *ORE1* plays a role in dark-induced senescence, *Arabidopsis* wild type plants, as well as *35S:ORE1* overexpressor line and the *anac092-1* T-DNA insertion mutant (Balazadeh *et al.*, 2010a), were assayed. As an additional control, plants transformed with an empty vector (E.V.) were included.

Senescence was artificially induced in *Arabidopsis* leaves by darkness. Detached leaves from 27-day-old plants corresponding to the lines described above were incubated for four days. Leaves were placed on moist filter paper and incubated at room temperature. As a control, detached leaves from the same lines were placed on moist filter paper under long-day photoperiod (16 hours of light; 8 hours of darkness). As seen in **Figure 4**, wild type *anac092-1* T-DNA insertion mutant and empty vector (E.V.) control leaves that were kept in a long-day photo period showed only slight yellowing in some leaves. Moreover, the tissue became dry in comparison to leaves placed in darkness. When compared to control detached leaves (E.V.), senescence was notably pronounced in leaves from the *35S:ORE1* overexpressor line that had been placed in darkness. Senescence was inhibited in leaves from the *anac092-1* T-DNA insertion mutant when compared to wild type leaves that had been placed in darkness. Thus, we suggest that *ORE1* constitutes a key transcriptional regulator of the dark-induce senescence network.

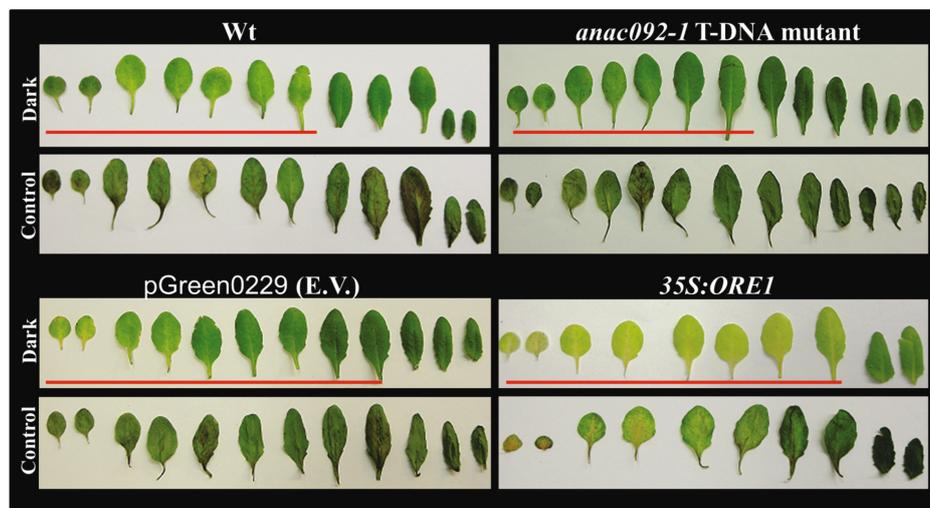

Figure 4. *ORE1* overexpression enhances the effect of dark-induced senescence in *Arabidopsis* leaves. Detached leaves from 27-day-old plants from wild type (Wt), *anac092-1* T-DNA insertion mutant, *35S:ORE1* overexpressor line, and Empty Vector (E.V.) control were placed in the dark. Leaves from E.V. and Wt served to compare the effect on *anac092-1* T-DNA insertion mutant and *35S:ORE1* overexpressor line, respectively. Control detached leaves from each tested line were placed in moist filter paper in open boxes. Overexpression of *ORE1* enhanced dark-induced senescence, whereas senescence was delayed in the *anac092-1* T-DNA insertion mutant. Underlined detached leaves exhibited the clearest comparative patterns.

2.2.3. Salt stress enhances *ORE1* expression

Screening of microarrays from public repositories revealed that *ORE1* was induced by salt stress in roots and shoots of *Arabidopsis* (Hruz *et al.*, 2008; Winter *et al.*, 2007). Furthermore, He *et al.* (2005) reported that intact ethylene and auxin signaling pathways are required for salt stress responsiveness in seedlings. To test if the response of *ORE1* to salt stress is regulated at the transcriptional level, *Arabidopsis Prom-ORE1:GUS* lines were grown on Murashige-Skoog (MS) (Murashige and Skoog, 1962) agar plates without salt. After 15 days, seedlings were transferred for 40 hours to a liquid MS medium containing 150 mM NaCl. GUS activity was enhanced in salt-treated seedlings compared to untreated controls (**Fig. 5.g-h**). We also analyzed *ORE1* promoter activity in transgenic tobacco plants (*Nicotiana tabacum*). Elevated GUS activity was observed in salt-treated (150 mM NaCl) leaves and other tissues including anthers, sepals, and petals (**Fig. 5.a-f**). The elevated expression of *ORE1* detected by histochemical analysis was confirmed by fluorometric measurements using 4-methylumbelliferyl-beta-D-glucuronide (4-MUG) and qRT-PCR (detailed information about these experiments has been published in Balazadeh *et al.*, (2010)).

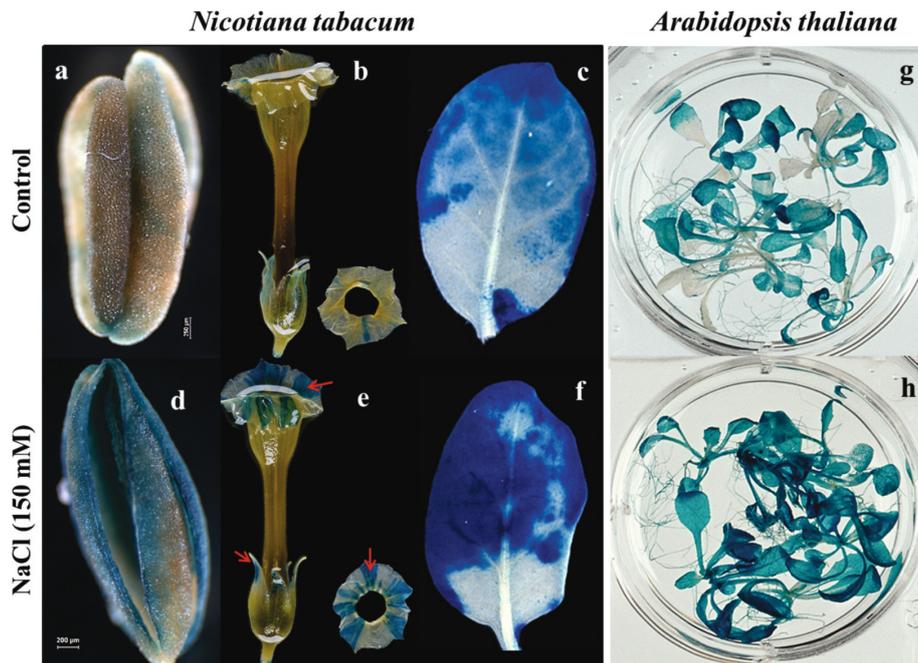

Figure 5. Salt stress activates transcription of the *ORE1* promoter. **Left panel.** GUS expression in different tobacco organs. (a) Anther, (b) flower, and (c) leaves were placed in water for 40 hours as controls. (d-f) Enhanced GUS activity in leaves and floral organs after 40 hours of salt treatment (150 mM NaCl). **Right panel.** Two-week-old *Arabidopsis* seedlings were treated for 40 hours with (g) 0 mM NaCl (Control) or (h) 150 mM NaCl.

2.2.4. *ORE1* senescence-specific expression is regulated by *cis*-elements in the 5'UTR

The specific relationship among gene regulatory networks is dependent on direct interactions between transcription factors and *cis*-regulatory elements (CREs) in promoter regions. One major area of study focuses on the understanding of the interaction between transcription factors and different CREs. Some well characterized CREs include the abscisic acid-responsive element (ABRE) (Marcotte Jr *et al.*, 1989; Mundy *et al.*, 1990), the dehydration-responsive element (DRE) (Yamaguchi-Shinozaki and Shinozaki, 1994), the C-repeat motif (Baker *et al.*, 1994), and the W-box (Rushton *et al.*, 1996), among others. Therefore, the elucidation of CREs that confers specificity in the expression of a given TF is crucial to understanding its regulatory pathway.

To gain further insights into the regulation of *ORE1* expression, promoter deletions were made to narrow down regions that confer the specific expression patterns observed (see patterns in **Fig. 3**). Results obtained with the long version of the *ORE1* promoter (1.5 kb) were described above (**section 2.2.1**). Two principle criteria were used to select the positions for the promoter deletions: (i) the presence of conserved sequences within the *ORE1* promoter, taking into consideration sequences that are present in orthologous promoters

from other plant species (**Fig. 6.A**); and (ii) the locations of CREs predicted to be present in the promoter (**Table 1**).

We produced two deletions that encompassed 230 bp (*Prom2-ORE1:GUS*) and 120 bp (*Prom3-ORE1:GUS*), respectively, up-stream of the start codon ATG, and transformed *Arabidopsis* plants. GUS staining patterns were determined in transgenic plants and compared with those obtained in plants harboring the 1.5 kb long up-stream region fused to the *GUS* reporter gene. The expression patterns were conserved in at least 70% of the evaluated plants (*Prom2-ORE1:GUS*; data not shown). The only visible difference between lines was a slight reduction in GUS activity in some senescent tissues, like leaves and cotyledons, of plants carrying the shortest version of the *ORE1* promoter (*Prom3-ORE1:GUS*) (see **Fig. 6**). Balazadeh *et al.*, (2011) analyzed conserved regions of *ORE1* up-stream of the ATG (1 kb up-stream of the ATG). This region included the 5'UTR regarded as a specific, highly conserved marker segment. Nevertheless, the analysis of the two truncated promoters described above suggested that a region proximal to the ATG is important to confer *ORE1* senescence-specific expression observed in leaves. Thus, we performed a comparative promoter analysis. First, we searched for clade orthologs of *ORE1* that exhibited high amino acid similarity using the Phytozome webpage (Goodstein *et al.*, 2012). The program performed a sequence alignment of all proteins in the platform against the sequence of *ORE1*. Any peptide similar to *ORE1* was listed with its percentage of similarity in parenthesis. *Arabidopsis lyrata* (97.2%), *Capsella rubella* (81.8%), *Brassica rapa* (89.8%), *Manihot esculenta* (69.5%), *Populus trichocarpa* (67.7%), and *Vitis vinifera* (67.7%) proteins were selected based on the highest similarity to *ORE1* from the species listed. The up-stream sequences of these genes, corresponding to the peptides, were retrieved and compared to the *ORE1* promoter (120 bp up-stream of the ATG). The MEME Suite web server (Bailey *et al.*, 2009) searched for conserved motifs to predict conserved putative regulatory elements (Bailey *et al.*, 2009). As shown in **Figure 6.A**, the selected up-stream sequences share conserved motifs among different plant species and may be taken as putative CREs important for *ORE1* tissue-specific expression. The program allowed us to define three different conserved motifs, although only the first and second motifs were present in *Arabidopsis thaliana*. Notably, the first motif identified in *Arabidopsis* is similar to the LE~5UTR-Py-rich stretch motif. This motif has been described as a CRE that confers a high transcription level without the need for further up-stream CREs except for a TATA-box (Daraselia *et al.*, 1996; Lescot *et al.*, 2002). Furthermore, this motif consists of highly conserved *ORE1* putative orthologs. The second motif is similar to a described light responsive AAAC-motif, and is placed around 50 bp up-stream of the ATG; it is only conserved between *Arabidopsis thaliana* and *Capsella rubella*. We performed a CRE analysis to identify previously described CREs present in the *ORE1* promoter (1.2 kb) (**Table 1**). This analysis led us to identify two LE~5UTR-Py-rich stretch motifs in the 5'UTR of *ORE1*. Despite the high similarity between the promoters of *ORE1* and *ORS1* (70%) (Balazadeh *et al.*, 2011), *ORS1* does not have a LE~5UTR-Py-rich stretch motif in the proximity of the ATG (data not shown). The motifs obtained by MEME

are similar to some CREs that have already been described. As shown in **Figure 6.A**, the region 100 bp up-stream of the ATG showed the presence of a motif highly similar to the LE~5UTR-Py-rich stretch motif (exact location -111 bp) and a second motif similarity to the AAAC-motif that corresponds to a light responsive motif (exact location 50 bp up-stream of the ATG).

To test if the CREs identified *in silico* may have relevance *in vivo*, we designed new deletions. The final constructs were designated *Prom4-ORE1:GUS*, *Prom5-ORE1:GUS*, and *Prom6-ORE1:GUS*. The regions covered by these constructs are schematically shown in **Fig. 6.B**. Three independent lines per construct were selected for further analysis. *Prom6-ORE1:GUS* lines that lacked the entire 5'UTR showed highly reduced GUS activity that was in some cases almost undetectable (see **Fig. 6.B**). In contrast, *Prom3-ORE1:GUS* lines, carrying a small fragment of the 5'UTR (120 bp) where one LE~5UTR-Py-rich stretch motifs lay, showed GUS activity in the tip and margin regions of senescent leaves (**Fig. 6.B**) and in cotyledons of seedlings (data not shown). Both expression patterns are characteristic features of the senescence syndrome. In **Figure 6.B**, it is shown that *Prom5-ORE1:GUS* lines carrying the same up-stream region as *Prom6-ORE1:GUS* lines, plus a short region of the 5'UTR, have the characteristic *ORE1* expression pattern in senescence leaves. The part of the 5'UTR present in *Prom5-ORE1:GUS* contains the other LE~5UTR-Py-rich stretch motif. Our data clearly show that *ORE1* promoter activity was highly dependent on the presence of the 5'UTR. In particular, the two LE~5UTR-Py-rich stretch motifs appeared to be necessary for the tissue-specific expression of *ORE1* during senescence. Nevertheless, a visible reduction of GUS activity in *Prom5-ORE1:GUS* and *Prom3-ORE1:GUS* lines suggests that other CREs outside the 5'UTR are needed to reach the high expression levels during senescence. Interestingly, the *ORE1* promoter contains more than 13 motifs described as light responsive elements and circadian regulatory elements within the first 1.0 kb up-stream of the ATG. One heat stress responsive element (HSE), a drought regulator element (MBS), and three TC-rich repeat elements involved in defense and stress responses are also predicted in the up-stream region (**Table 1**). These data are in good agreement with our findings regarding dark-induced senescence (see **section 2.2.2**) and *ORE1* activity in wounded leaves (see **section 2.2.2**) and in response to salt stress (see **section 2.2.3**). Further experiments are required to confirm which of these predicted CREs are, in fact, involved in dark-induced, salt stress, and wounded responsiveness of *ORE1*.

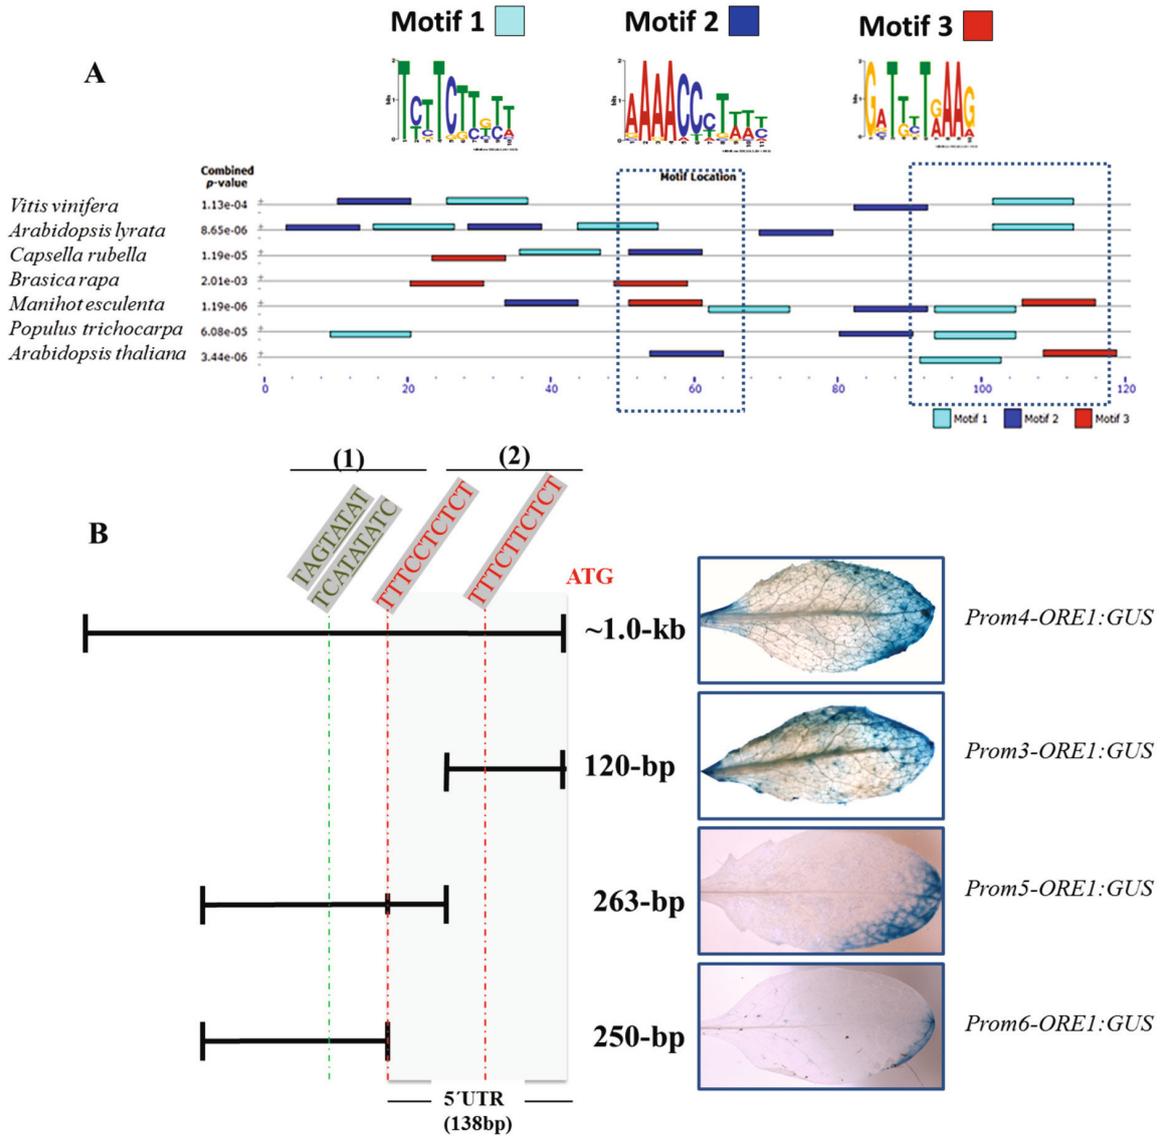

Figure 6. Deletion analysis of the *ORE1* up-stream region. (A) Non-coding sequences conserved in the *ORE1* promoter and six *ORE1* orthologs (120 bp up-stream of the ATG). The first motif is highly similar to the LE~5UTR-Py-rich stretch motif and is highly conserved in the promoters of *ORE1* orthologs (B) Four different deletions in the *ORE1* promoter showed that the decrease of *ORE1* expression is dependent on the presence of the 5'UTR. Boxes shown in colors indicate CREs predicted by the PlantCARE database (Lescot *et al.*, 2002). (1) Represents the sites of two predicted TATA-boxes. (2) Represents two predicted LE~5UTR-Py-rich stretch motifs (positions -111 and -136 from the ATG) that may confer high transcription levels (Daraselia *et al.*, 1996).

2.2.5. ATAF1 positively regulates *ORE1* expression

The identification of the crosstalk between different signal transduction pathways, especially in relation to senescence, abiotic stress tolerance, and leaf growth in general, is a major task in our research group. Based on transcriptional profiling of lines overexpressing the NAC TF *ATAF1* under the control of an estradiol-inducible promoter (after 10 hours and 24 hours of estradiol induction), *ATAF1* was identified as a potential up-stream activator of *ORE1* (Fig. 7). Like *ORE1* (At5g39610), *ATAF1* (At1g01720) also encodes a NAC TF; both have

been reported as senescence associated genes (SAGs) (Buchanan-Wollaston *et al.*, 2005; Balazadeh *et al.*, 2008b). Additionally, both genes are regulators of common signaling pathways related to drought and wounding responses, salt stress response, (Balazadeh *et al.*, 2010a,b; Buchanan-Wollaston *et al.*, 2005; Mauch-Mani and Flors 2009; Wu *et al.*, 2009), and defense response (Al-Daoud and Cameron 2011; Collinge *et al.*, 2008; Wang *et al.*, 2009).

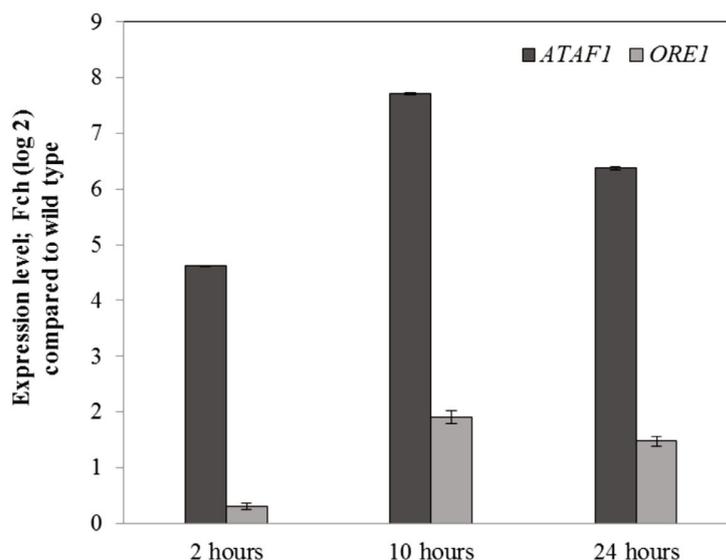

Figure 7. Transcription levels of *ORE1* and *ATAF1* in *ATAF1* inducible overexpressor (*ATAF1-IOE*) lines upon estradiol (EST) induction. *ORE1* transcript abundance increased concomitantly with *ATAF1*. Maximal level of *ORE1* transcript abundance was reached after 10 hours of EST induction.

The induction of *ORE1* upon inducible overexpression of *ATAF1* suggests a possible direct control of *ATAF1* over *ORE1* and, by this, the regulation of natural and stress-induced senescence. In order to test a direct interaction *in vivo* between *ATAF1* and *ORE1*, I used protoplast transactivation assays. The *ORE1* promoter (1.0 kb up-stream of the ATG) was amplified by PCR from *Arabidopsis* genomic DNA (ecotype Col-0), cloned into the pENTR/D-topo vector (Invitrogen), and then recombined into the Gateway-compatible destination vector *p2GWL7.0* (Karimi *et al.*, 2002) to obtain the final reporter vector *ORE1-LUC*. The effector plasmid was the *35S:ATAF1* construct. For detailed descriptions, see **sections 2.4.3 and 2.4.7**. Briefly, a dual-reporter system determines the transcriptional activation of the *ORE1-LUC* promoter. Activation is detected by the relative light emitted from firefly luciferase (LUC) enzymatic activity. The internal control reporter, *Renilla* luciferase (*35S:RLuc*) (Licausi *et al.*, 2011) provides the parameter to normalize the data and calculate *ORE1-LUC* promoter activity (**Fig. 8.A**). *Arabidopsis* mesophyll cell protoplasts co-transfected with the *ORE1-LUC* and *35S:ATAF1* constructs showed high luciferase activity indicating an activation of the *ORE1* promoter by the *ATAF1* TF (**Fig. 8.B**).

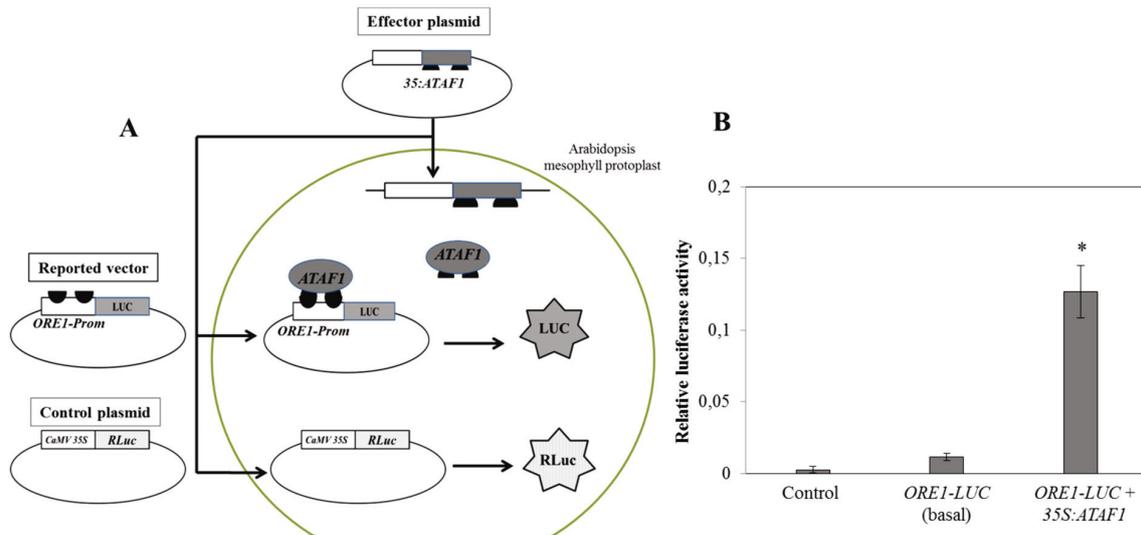

Figure 8. Protoplast transactivation assay of ATAF1 and *ORE1* promoter. **A.** Schematic representation of the transactivation assay. Effector and reporter/control vectors are shown. **B.** Relative luciferase activity detected in mesophyll cell protoplasts co-transfected with *ORE1-LUC* and *35S:ATAF1*. Results are the mean of two biological replicates with three technical replicates per probe. Data were normalized to the corresponding *Renilla* luciferase activity. * $P < 0.05$.

2.3. Conclusions

In this study we confirmed the evolutionary conservation of *ORE1* expression in two different plant species (*Arabidopsis thaliana* and *Nicotiana tabacum*). The conservation of *ORE1* expression is extended from early mature embryos and primary roots until advanced stages of aging. Also the responsiveness to salt stress of *ORE1* is conserved in both species. We found that *ORE1* positively regulates dark-induced senescence. The characterization of the *ORE1* promoter led us to suggest that the 5'UTR plays an important role in mediating the characteristic expression pattern observed during natural senescence. *ORE1* is transcriptionally activated by another NAC transcription factor, *ATAF1*. Considering that *ATAF1* has been reported as a senescence associated gene (SAG) (Buchanan-Wollaston *et al.*, 2005; Balazadeh *et al.*, 2008b) and that *ATAF1* activates the expression of *ORE1*, we propose *ATAF1* as a positive regulator of *ORE1* in the regulatory pathway that mediates age-dependent senescence. Further analyses are required to confirm direct regulation of *ORE1* by *ATAF1*.

2.4. Experimental procedures

2.4.1. General

Standard molecular techniques were performed as described (Sambrook and Russell, 2001). Oligonucleotides were obtained from MWG (Ebersberg, Germany). DNA sequencing was performed by MWG. Unless otherwise indicated, other chemicals were purchased from Roche

(Mannheim, Germany), Merck (Darmstadt, Germany), or Sigma (Deisenhofen, Germany). The *Arabidopsis* Information Resource (TAIR; <http://www.Arabidopsis.org/>) and the Plant Transcription Factor Database (<http://plntfdb.bio.uni-potsdam.de/v2.0/>) were used to obtain CDS and promoter sequences. The tools used for sequence analyses were provided by the National Center for Biotechnology Information (<http://www.ncbi.nlm.nih.gov/>) and NCBI's BLAST database/genebank (<http://blast.ncbi.nlm.nih.gov/Blast.cgi>) (Altschul *et al.*, 1997). qRT-PC reactions were conducted using an ABI PRISM 7900HT sequence detection system (Applied Biosystems Applied). Except for those already published, primers used during this study are described and codified by an internal labor code (**Annex 1**).

2.4.2. Plants and growth conditions

All *Arabidopsis thaliana* lines used were in the wild type (Col-0 ecotype) background. Seeds from *Arabidopsis* and tobacco were surface sterilized with 70% ethanol (1 minute), 20% sodium hypochlorite (30 minutes) and rinsed with sterile water (six times). *Arabidopsis* seeds were immediately germinated on Murashige–Skoog (MS) half-strength medium (Murashige and Skoog, 1962) supplemented with 7% agar and 1% sucrose. Seeds were stratified for 48 hours in the dark at 4°C and then transferred into a climate chamber with 16 hours of day light provided by fluorescent light at 100 $\mu\text{E m}^{-2} \text{sec}^{-2}$ intensity and a day/night temperature of 20/16°C and relative humidity (RH) of 60/75%. In the case of tobacco, plants were grown with 16 hours of day light at 25°C and 8 hours of darkness (20°C). The homozygous T-DNA insertion line (*anac092-1* T-DNA insertion mutant) originated from the SALK collection (ID 090154) described in Balazadeh *et al.* (2010a). In cases where plants were grown directly on soil, seeds were stratified for one week at 4°C, then transfer to long-day photoperiod in phytotron and after two weeks transferred into a climate chamber with 16 hours of day light provided by fluorescent light at 100 $\mu\text{E m}^{-2} \text{sec}^{-2}$ intensity and a day/night temperature of 20/16°C and relative humidity (RH) of 60/75%.

2.4.3. Constructs

Description of the ***Prom-ORE1:GUS*** and the ***35S:ORE1*** overexpressor line were given in Balazadeh *et al.*, (2010a).

Prom3-ORE1:GUS. A 120 bp genomic fragment up-stream of the start codon (ATG) of *ORE1* (At5g39610) was amplified by a polymerase chain reaction (PCR) using forward (110) and reverse (111) primers. The isolated fragments were inserted first into plasmid pCR2.1-TOPO (Invitrogen), and after sequencing were fused via *BamHI* and *NcoI* sites to the GUS reporter gene into *pCAMBIA1305*. 1-hygromycin (CAMBIA).

ORE1:GUS promoters. The promoter regions corresponding to 1.0 kb, 263 bp, and 250 bp up-stream of the ATG, respectively, were amplified from genomic DNA by PCR using an Advantage HF 2 PCR Kit (Clontech) with gene-specific forward and reverse primer sets for

each promoter region (**Annex 1**). The fragments were subcloned into a pENTR-D-TOPO vector (Invitrogen) to generate the entry vectors *pProm4-*, *pProm5-*, and *pProm6- ORE1-ENTRY*. Entry vectors were recombined into Gateway destination vector *pKGW7.0* using the LR reaction mix II (Invitrogen) to obtain the final reporter vectors *Prom4-*, *Prom5-*, and *Prom6- ORE1:GUS*.

ORE1-LUC. This vector was used as a reporter vector in the transactivation assays (**section 2.2.5**). The *pProm4-ORE1-ENTRY* entry vector was recombined into Gateway destination vector *p2GWL7.0*, which is a recombination of the gateway vectors *pBGWL7.0* (transcription reporter vector) and *p2GW7.0* (overexpression vector) (Licausi *et al.*, 2011) using the LR reaction mix II (Invitrogen) to obtain the final reporter vector *ORE1-LUC*.

ATAF1-IOE. PCR was used to amplify the *ATAF1* (At1g01720) coding region using *Arabidopsis* Col-0 leaf cDNA as a template and by using forward (204) and reverse (205) primers (**Annex 1**). The *ATAF1* cDNA was inserted into the pCR2.1-TOPO vector and, after sequence confirmation, cloned via *XhoI* and *SpeI* sites into the pER-8 vector (Zuo *et al.*, 2000).

35S:ATAF1. The vector was used as effector plasmid in transactivation assays (**section 2.2.5**). The *ATAF1* (At1g01720) coding region was amplified by PCR using a combination of forward (206) and reverse (207) primers (**Annex 1**) and by using *Arabidopsis* Col-0 leaf cDNA as a template, and then it was inserted into pUni/V5-His-TOPO (Invitrogen). After sequence confirmation, the cDNAs were cloned via added *PmeI/PacI* sites into a modified pGreen0229 plant transformation vector (www.pgreen.ac.uk) containing the Cauliflower Mosaic Virus (*CaMV*) 35S promoter located in the *PmeI/PacI* restriction sites (Skirycz *et al.*, 2006).

2.4.4. Plant transformation

Agrobacterium tumefaciens strain GV2260 and GV3101 (pMP90) containing specific *ORE1* promoter deletions fused to the *GUS* reporter gene were used to transform tobacco and *Arabidopsis*, respectively. In all cases, positive clones were confirmed by PCR and sequencing. *Agrobacterium* cultures were grown overnight (O.N) in constant agitation (200 rpm) at 28°C in liquid Yeast –Extract –Broth (YEB)/ rifampicin (50 mg/ml)/gentamicin (20 mg/ml) and the bacterial resistance marker antibiotic hygromycin (10 mg/ml). In the case of *Arabidopsis*, wild type (Col-0) flower buds were immersed in the suspension of *A. tumefaciens* and transformed by dipping method (Bechtold and Pelletier, 1998; Clough and Bent, 1998). In the case of tobacco plants, a transformed *Agrobacterium* pellet was collected by centrifugation (4000 rpm) for 10 minutes at room temperature (RT). The pellet was resuspended in 10 mL (10 mM) MgSO₄. Leaf squares of tobacco plants grown *in vitro* (max. 4-week old) were placed in resuspended bacteria for 3-4 minutes. Leaf squares were transferred to MS media for two days and placed in the dark and RT. The callus formation

initiated in only putative transformed leaf squares; untransformed leaf squares yellowed after 3-5 days. The transformed leaflets developed into bright white-green calluses and were transferred to shoot induction tobacco media containing gentamicin (20 mg/mL) and carbenicillin (500 mg/L).

2.4.5. Histochemical GUS assay

Histochemical *in situ* staining was used to determine the expression pattern in different tissues of transformed-GUS plants. Plant tissues at different developmental stages were submerged in a staining solution of 50 mM sodium phosphate pH 7.0, 0.1% (v/v) Triton X-100, 0.1 mM potassium ferricyanide, 0.1 mM potassium ferrocyanide, 1 mM Na₂ EDTA pH 8.0, 20% (v/v) methanol, and 0.5 mg/mL 5-bromo-4-chloro-3-indolyl-b-D-glucuronid acid (X-gluc; Duchefa). Samples were incubated at 37°C for a period of several hours to overnight depending on the tissue type, construct, and color rate. Chlorophyll was removed by submerging the samples in ethanol 70% (v/v). GUS staining was visualized using a stereomicroscope Leica MZ 12,5 with software LAS (Leica).

2.4.6. Dark-induced senescence

Experiments for artificial induction of senescence were performed with all rosettes leaves of 27-day-old plants from wild type (Wt), *anac092-1* T-DNA insertion mutant, *35S:ORE1* overexpressor line and Empty Vector (E.V.). Detached leaves were incubated in the dark into boxes on moist filter paper during four days at RT (room temperature). As control detaches leaves from the same lines were placed on moist filter paper under long-day photoperiod (16 hours light; 8 hours darkness) on moist filter paper. In both cases filter papers were maintained always humid.

2.4.7. Salt treatment for *Arabidopsis* and tobacco plants

Arabidopsis seedlings were grown in long-day conditions (section 2.4.2) and after two weeks were transfer to liquid media and treated for 40 hours with 0 mM NaCl (Control) or 150 mM NaCl. In the case of tobacco, detached leaves and flowers from different developmental stages were isolated from mature tobacco plants (five months after sowing) and treated for 40 hours with 0 mM NaCl (Control) or 150 mM NaCl. Immediately after treatment, tobacco and *Arabidopsis* seedlings were stained with GUS buffer as described in section 2.4.5.

2.4.8. Dual-luciferase assay

This experimental procedure was used in different assays, and for this reason, the description will be given as a general protocol. Promoter regions of *ORE1* putative target genes were used as reporter plasmids: a 1.0 kb up-stream of the translation start site were amplified

from genomic *Arabidopsis* ecotype Col-0 DNA to generate reporter final constructs. A detailed description of each *prom-LUC* construct is described in the experimental procedure section of each chapter. In this case, we used *ORE1-LUC* construct as the reporter (**section 2.4.3**). Renilla luciferase CDS was amplified using pRL-null (Promega) as a template. The resulting amplicon was ligated into the pENTR/D-topo vector (Invitrogen) and subsequently recombined in *p2GW7* (Karimi *et al.*, 2002) using the LR clonase enzyme (Invitrogen) to generate the *35S:RLuc* normalization vector (Licausi *et al.*, 2011). A *35S:ATAF1* construct was used as effector plasmid (described in **section 2.4.3**). The effector, reporter, and reference plasmids were co-transfected into mesophyll cell protoplasts that were prepared from rosette leaves of 4-week-old *Arabidopsis* plants, as reported by Sheen (Sheen, 2002). The protoplasts had a maximum reaction volume of 10 ul and contained 6.0 ug DNA of each construct. Luciferase activity was assayed with the Dual Luciferase Reporter Assay System (Promega), and the luminescence was read in a GloMax 2020 Luminometer (Promega). All tests were performed in 3-4 independent biological replications with three technical replications per assay. Assays by t-test using the SigmaPlot software (<http://www.sigmaplot.com>) were statistically significant.

2.4.9. cDNA synthesis and quantitative real-time PCR (qRT-PCR)

Total RNA extraction, cDNA synthesis, and qRT-PCR were done as previously described (Balazadeh *et al.*, 2008b; Caldana *et al.*, 2007). Primer sequences used for qRT-PCR analysis to quantify transcript levels of *ORE1* (At5g39610) and *ATAF1* (At1g01720) are given in **Annex 1**. The PCR reactions were run on an ABI PRISM 7900HT sequence detection system (Applied Biosystems Applied). At least five measurements were carried out to determine the mRNA abundance of each gene in each sample. The absence of genomic DNA was verified by PCR using forward (202) and reverse (203) primers designed to amplify an intergenic region in a control gene (At5g65080). cDNA was produced from 2.0 µg total RNA using SuperScriptT III Reverse Transcriptase (Invitrogen). cDNA synthesis efficiency was controlled by qRT-PCR amplification of a housekeeping gene *ACTIN2* (At3g18780) using specific forward (204) and reverse (205) primers (**Annex 1**). Data analysis was performed using SDS 2.2.1 software (Applied Biosystems Applied). Amplification curves were analyzed with a normalized reporter (R_n : the ratio of the fluorescence emission intensity of SYBR Green to the fluorescence signal of the passive reference dye) threshold of 0.2 to obtain C_T values (threshold cycle). Dates were normalized to *ACTIN2* as follows $\Delta C_T = C_T$ (gene) - C_T (*ACTIN2*). The expression was measured with three replicates in each PCR run, and the average C_T was used for relative expression analyses. Relative transcript abundance was determined using the comparative $\Delta\Delta C_T$ method ($\Delta\Delta C_T = \Delta C_T$ (condition of interest) - ΔC_T (control condition)), and the Fold Change (Fch) was calculated using the expression $2^{-\Delta\Delta C_T}$, where the obtained results were Log_2 transformed. In some cases, the expression was expressed as $40^{-\Delta\Delta C_T}$ to improve visualization.

Contributions

The *Prom1-ORE1:GUS*, *ORE1-IOE*, *35S:ORE1* lines and *anac092-1 T-DNA* insertion mutant screening were performed by Dr. Hamad Siddiqui (Molecular Biology, Potsdam University). *ATAF1-IOE* constructs were provided by Dr. Dagmar Kupper (Molecular Biology, Potsdam University). *35S:ATAF1* construct and *ATAF1* transcriptome data were provided by Prashant Garapati, Ph.D student of Prof. Dr. Mueller-Roeber's Group.

Chapter 3

A calcium-dependent protein kinase CKOR positively regulates the expression of three ORE1 putative target genes

This work has been developed through a collaboration with Prof. Tina Romeis's Group (Biochemistry of Plants Group, Institute of Biology, Freie Universität Berlin)

3.1. Introduction

Cells are exposed to a broad spectrum of internal and external stimuli. The cell-to-cell interactions during development, as well as the environmental fluctuations and stresses, constitute messages that need a correct integration into the molecular signaling pathways to generate specific and appropriate responses (Krebs, 1993). Signal transduction frames include post-transcriptional modification of sundry proteins by kinases. During protein phosphorylation, protein kinases covalently link phosphate groups to the target proteins (Feilner *et al.*, 2005). Calcium-dependent protein kinases (CDPKs) are a group of serine/threonine kinases that are regulated by a Ca^{+2} / calmodulin complex. Therefore, calcium-stimulated kinase activities could be activated by direct calcium binding (Cheng *et al.*, 2002). Because osmotic stress elicits calcium signaling (Knight *et al.*, 1997), calcium-dependent protein kinases are prime candidates that link the calcium signal to down-stream responses (Zhu, 2002).

In order to interact with their target DNA sequences, transcription factors (TFs) need to be located in the cell nucleus. Several TFs are constitutively nuclear, and phosphorylation and dephosphorylation by protein kinases and protein phosphatases take place within the nucleus. However, TFs can be mobilized between cytoplasm and the nucleus, and in many cases this mobilization is regulated by phosphorylation/dephosphorylation (Whitmarsh and Davis, 2000). DNA binding activity of TFs may also be regulated indirectly by phosphorylation at residues that are remote from the DNA binding domain. The deletion of genes that encode protein kinases and protein phosphatases that target particular transcription factors, as well

as targeted mutations of the codons that encode the phosphoacceptor sites on TFs, provide genetic evidence for the importance of these signaling molecules in regulating particular functions of a transcription factor (Whitmarsh and Davis, 2000). For instance, the NAC transcription factor *ORE1* has been reported as a putative substrate of the mitogen-activated protein kinases (MPKs) MPK2, MPK5, MPK8, and MPK10 *in vitro* (Popescu *et al.*, 2009). However, the implications in planta of this modification remain unknown.

A phosphoproteomic approach using transgenic lines that were overexpressing a CDPK named CKOR (for calcium-dependent kinase regulating ORE1) revealed ORE1 is one of the few proteins differentially phosphorylated (unpublished data, Biochemistry of Plants Group, Prof. Tina Romeis, Freie Universität Berlin). We determined that the overexpression of ORE1 led to a significant increase in the transcriptional activation of three putative target genes of ORE1 (*BFNI*, *VNI2* and *RNS3*) *in vivo*, and that ORE1 binds directly to the promoters of their putative targets (see Chapter 4). Furthermore, *BFNI*, *VNI2*, and *ORE1* are senescence associated genes (SAGs) (Balazadeh *et al.*, 2008a; Breeze *et al.*, 2011; Buchanan-Wollaston *et al.*, 2005; Guo *et al.*, 2004), and *RNS3* is involved in inorganic phosphate (Pi) remobilization during Pi starvation and senescence. The molecular mechanisms initiated by nutrient remobilization during senescence are poorly characterized, but in the case of Pi starvation, ribonucleases are considered to play important roles in the remobilization process (Bariola *et al.*, 1994). Here, we show that the transcriptional activation of *BFNI* (At1g11190), *VNI2* (At5g13180), and *RNS3* (At1g26820) is strongly influenced by the co-expression of CKOR. Mesophyll protoplasts co-transfected with CKOR showed an increase in transcriptional activity, while protoplasts co-transfected with a mutated version of CKOR (that renders an inactive kinase) showed a marked decrease in the transcriptional activity of *BFNI*, and they left the activity of *VNI2* and *RNS3* undistinguishable from the basal activity.

3.2. Results

3.2.1. CKOR influences the transcriptional activation of ORE1 direct targets

ORE1 is a key regulator of natural and induced senescence, and evidences suggest that interaction to *BFNI*, *VNI2* and *RNS3* could play an important role in senescence regulation. In an effort to identify the effect of *ORE1* phosphorylation by CKOR, we tested the expression of ORE1 targets in cells co-transformed with two different versions of CKOR. The promoter regions (1.0 kb up-stream of the start codon (ATG)) of *BFNI*, *RNS3*, and *VNI2* were cloned into the Gateway destination vector *p2GWL7.0* (Licausi *et al.*, 2011) that contains the firefly luciferase reporter gene (*LUC*). Thus, the expression of *LUC* is under the transcriptional control of each promoter. The final vectors *BFNI-LUC*, *RNS3-LUC*, and *VNI2-LUC* (**Chapter 4, section 4.4.4**) were used as reporters. Two different versions of CKOR were used as effector vectors: either the wild type version of the protein (CKORac), or a mutated version (CKORm) where one aspartic acid is replaced by alanine in the catalytic domain (rendering

the kinase inactive) (see **section 3.4.3**). As an internal control, we used reporter *Renilla* luciferase (*35S:RLuc*) (Licausi *et al.*, 2011) to normalize the data and calculate the activity of each tested promoter. We co-transfected *Arabidopsis* wild type mesophyll cell protoplasts in a series of protoplast transactivation assays using the PEG method (Sheen, 2002). Each *promoter-LUC* construct and *35S:RLuc* were co-transfected with/without CKORac (active form) or with/without CKORM (inactive form). In each case, we evaluated the promoter activation upon overexpression of CKOR (active or mutated) as well as the basal promoter expression.

All promoters showed a basal activity (*BFNI*, *VNI2*, and *RNS3*), likely due to the TFs present in the protoplasts (including *ORE1*) that can activate these promoters. *BFNI* exhibited the stronger basal activity (10-fold) compared to *VNI2* or *RNS3*. Thus, we inferred that protoplasts from five-week-old plants have a stronger *BFNI* expression than *VNI2* or *RNS3* (**Fig. 9.A**). Co-transfection with a catalytically active CKOR protein (CKORac) increased the expression of all promoters tested in comparison to the basal expression (**Fig. 9.A-C**). In contrast, co-transfection with the catalytically inactive CKOR (CKORM) resulted in a transcriptional activity undistinguishable from the basal activity for *VNI2* and *RNS3*, and a significant decrease of transcriptional activity in the case of *BFNI* (**Fig. 9.D-F**).

To explain the increase in transcriptional activation observed in *BFNI*, *VNI2*, and *RNS3* upon co-transfecting with CKORac (**Fig. 9.A-C**), we hypothesized that CKORac overexpression may have resulted in increased ORE1 phosphorylation that, in turn, increased the activation level of its direct targets. These results provide some insights into the role of CKOR as a positive regulator of *BFNI*, *VNI2*, and *RNS3* perhaps through the phosphorylation of the transcription factor *ORE1* (**Fig. 9.A-C**).

On the contrary, the overexpression of CKORM, which is unable to phosphorylate its targets, led to a decreased level of *BFNI* promoter activity and a decrease in activities that are undistinguishable from the basal activity for the promoters of *VNI2* and *RNS3*. This result may indicate that the overexpression of CKORM, which is unable to phosphorylate ORE1 (although is able to bind the protein), hinders the normal activity of ORE1. Thus, an excess of CKORM leads to an even lower *BFNI* promoter activity. The basal activity of the other tested promoters (*VNI2* and *RNS3*) is already so low at the starting conditions that overexpression of CKORM has just a minor effect on these promoters. Currently, our collaborating partner (Biochemistry of Plants Group, Prof. Dr. Tina Romeis, Freie Universität Berlin) is carrying out further experiments to unravel detailed interactions between CKOR and ORE1.

3.3. Conclusions

We suggest that ORE1 is post-transcriptionally regulated by CKOR. The phosphorylation of ORE1 plays a crucial role in its activity and favors the transcriptional activation of its targets

BFN1, *VNI2*, and *RNS3*. Nevertheless, phosphorylation seems to affect the activation of *BFN1* more severely than the other promoters. These results provide important information related to additional mechanisms influencing the activity of ORE1.

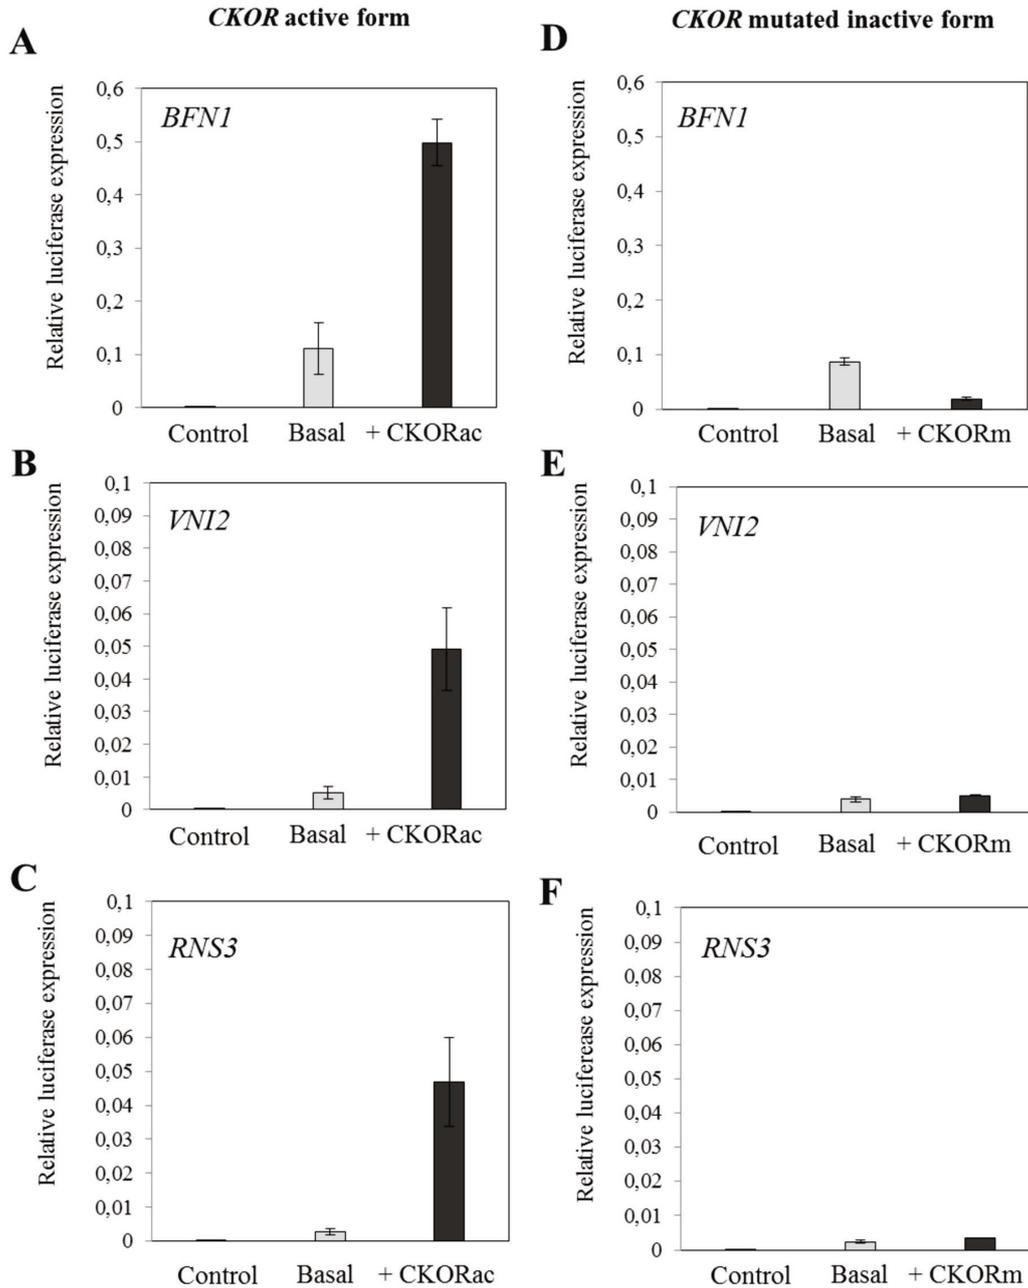

Figure 9. Activation of ORE1 direct targets by CKOR. (A-C) Co-transfection of *BFN1:LUC*, *VNI2:LUC*, and *RNS3:LUC* with *35S:RLuc* and with or without (basal) CKORac (active form). (D-E) Co-transfection of *BFN1:LUC*, *VNI2:LUC* and *RNS3:LUC* with *35S:RLuc* and with or without (basal) CKORM (inactive form). Data represent mean values \pm standard deviation (SD) (n=2) 3 technical replicates. Luciferase values are normalized to the corresponding Renilla expression level.

3.4. Experimental procedures

3.4.1. General

Standard molecular techniques were performed as described in **Chapter 2, section 2.4.1.**

3.4.2. Plant material

Plant material and growth conditions were similar to those described in **Chapter 2, section 2.4.2.**

3.4.3. Constructs

Promoter-LUC constructs: promoter regions spanning 1.5 kb up-stream of the ATG of *VNI2*, *BFNI*, and *RNS3* were amplified from genomic DNA by PCR using an Advantage HF 2 PCR Kit (Clontech) with gene-specific forward and reverse primers (**Annex 1**). Promoter fragments were subcloned into pENTR-D-TOPO vectors (Invitrogen), to generate individual entry vectors. The entry vectors were then recombined into a *p2GWL7.0* Gateway destination vector which is a recombination of the *pBGWL7.0* gateway vector (transcription reporter vector) (Karimi *et al.*, 2002) and *p2GW7.0* vector (overexpression vector) (Licausi *et al.*, 2011)) using the LR reaction mix II (Invitrogen) to obtain the final *BFNI-LUC*, *VNI2-LUC*, *RNS3-LUC* reporter vectors.

CKORac and CKORM: Plasmids containing the constitutively active and mutated versions of CKOR in the pXCS-G-StrepII binary vector were kindly provided by G. Durian (Freie Universität Berlin). This vector uses the pamPATMCS backbone (accession number AY436765) and allows convenient and rapid expression of proteins *in planta* (Witte *et al.*, 2004). The effectors vectors are named *CKORac* and *CKORM* for normal (active) and mutated (inactive) versions, respectively.

3.4.4. Dual-luciferase assay (Transactivation assay)

A detailed description of the procedure was given in **Chapter 2, section 2.4.7.** Based on previous data (data not shown) for this particular assay, the time of protoplast co-transfection was decreased from 24 hours to 14 hours to avoid tissue damage and cell death.

Chapter 4

Inferring putative targets of ORE1 through transcriptome-based expression analysis

Part of this work will be submitted to *The Plant Journal* with the title:

“Expression of *BIFUNCTIONAL NUCLEASE1 (BFNI)* during senescence in *Arabidopsis* is regulated by the NAC transcription factor ORE1/ANAC092/AtNAC2”

4.1. Introduction

Plant senescence is a highly regulated process that involves many regulatory proteins, including transcription factors (TFs), which control the expression of target genes and constitute up-stream control elements of gene regulatory networks (GRNs). ORE1, a NAC TF, has recently been shown to be a central regulator of senescence in *Arabidopsis thaliana* (Balazadeh *et al.*, 2008; Balazadeh *et al.*, 2010a; Kim *et al.*, 2009). In our previous work, we identified ORE1 responsive genes using estradiol-inducible overexpressor lines (*ORE1-IOE*) (Balazadeh *et al.*, 2010a). Many of the up-regulated genes encode proteins known to function in the degradation of different macromolecules as part of the mechanism of

nutrient salvage that occurs in plants during senescence (Bleecker, 1998). The ORE1 regulon includes proteins involved in further signal transduction pathways such as other TFs (NAC TF among them). In this study, in order to identify direct target genes of ORE1, additional global transcriptome analyses were carried out. Inducible ORE1 overexpressing plants (*ORE1-IOE*) were incubated for two hours in estradiol (EST). To account for artifacts caused by the use of EST, further global expression profiling experiments were made using *Arabidopsis* mesophyll cell protoplasts transformed with a *35S:ORE1* construct and harvested six hours after transfection. We determined the ORE1 binding site (BS) and its frequency within the promoter regions of putative target genes. Additionally, our results showed that ORE1 is able to bind to the promoters of *BFN1*, *VNI2*, and *RNS3* *in vitro* and to transactivate them *in vivo*. Our data strongly suggests that *BFN1*, *VNI2*, and *RNS3* are putative direct targets of ORE1.

4.2. Results

4.2.1. Transcriptome profiling reveals a core set of putative ORE1 direct targets

In our previous study, we observed that after five hours of estradiol induction, 218 genes were differentially expressed. From these, 170 were significantly up-regulated and 48 were significantly down-regulated (Balazadeh *et al.*, 2010a). In this study, in order to identify direct targets of ORE1, additional expression profiling experiments were carried out using cells/plants that were overexpressing *ORE1* constitutively (using the strong constitutive promoter 35S (CaMV) Cauliflower mosaic virus) or inducibly (using an estradiol-inducible promoter). Log₂ intensity values were converted to Log₂ fold change ratios by comparing the intensity of induced/transformed and uninduced/untransformed plants/cells. Differentially expressed genes were determined by setting a twofold cut-off ($\text{Log}_2 \pm 1$). Our data revealed that 78 genes were differentially expressed after two hours EST induction in *ORE1-IOE* plants. From these genes, 54 were up- and 24 were down-regulated (**Annex 3**). After five hours of EST induction in our new profiling experiments, 269 genes were differentially expressed. From these, 195 genes were up- and 74 were down-regulated (**Annex 4**). Six transcription factors were identified after five hours ORE1 induction including one zinc-ion binding factor (At2g28200), one signal transduction response regulator (At2g40670), one *MYB TF* (At3g10590), and three members of the NAC TF family (*ANAC010*, *ANAC041*, and *VNI2*). In our datasets, we observed that the number of up-regulated genes after EST induction increased around fourfold (from 54 after two hours to 195 after five hours). Among them, only less than 1.0% overlapped (two genes). The number of down-regulated genes increased threefold (from 24 after two hours to 74 after five hours), and none overlapped between datasets. Upon transient overexpression of ORE1 in mesophyll protoplasts, 831 genes were found differentially expressed, of which 643 were up- and 188 were down-regulated (**Annex 5 only in the electronic version**). Venn diagrams show overlapping up- (**Fig. 10.A**) or down-regulated genes among datasets (**Fig. 10.B**). Taking together all datasets, 731 genes were significantly up-regulated while 273 were significantly down-regulated upon ORE1

overexpression. There is a larger overlap between genes up- or down-regulated from five to six hours overexpression (144 up- and 10 down-regulated) than from two to five hours overexpression (**Fig. 10.A-B**). Interestingly, there were no common down-regulated genes among the three datasets (**Fig. 10.B**). We were able to identify a set of 17 commonly up-regulated genes among the three datasets (**Fig. 10.A**).

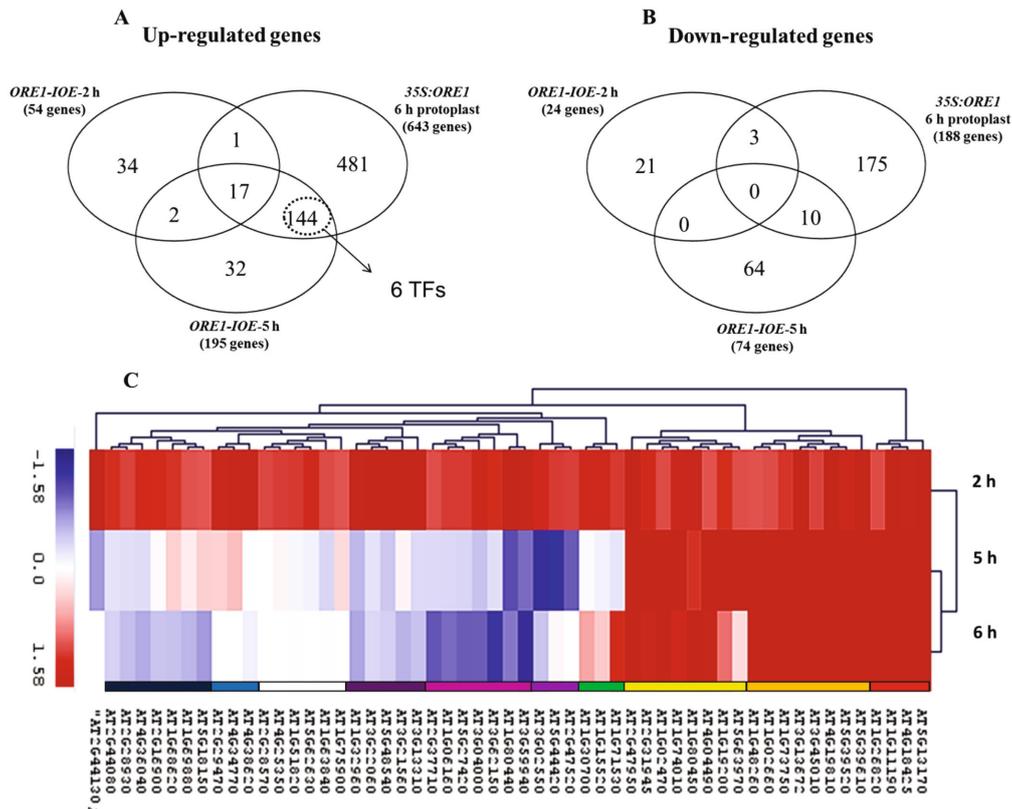

Figure 10. Differentially expressed genes in plants/cells overexpressing ORE1. (A-B) Venn diagrams to compare up/down-regulated genes in *ORE1-IOE-2* hours plants, *ORE1-IOE-5* hours plants, and *35S:ORE1-6* hours protoplasts. (C) Hierarchical clustering based on 54 up-regulated genes after two hours of EST induction (*ORE1-IOE* plants). Ten clusters were identified and color coded from right to left.

The cluster analysis, based on genes significantly up-regulated in *ORE1-IOE* plants induced for two hours with EST (54 genes), revealed ten different patterns of expression when compared to datasets two (*ORE1-IOE* induced five hours with EST) and three (constitutive overexpression for six hours in protoplasts). In **Figure 1.C**, cluster 1 (in red) includes highly up-regulated genes in all data-sets. Clusters 2 and 3 (in light and dark yellow, respectively) include highly up-regulated genes in at least two datasets and less induced in the other. Cluster 4 (in green) encompasses up-regulated genes in data set one and three, but not differentially expressed or slightly down-regulated genes in data set two. Clusters 5, 6, and 7 (in different shades of magenta) group up-regulated genes in data set one and not differentially expressed or slightly down-regulated genes in datasets two and three. Cluster 8 (in white) groups up-

regulated genes in data set one, slightly up/down-regulated genes in data set two, and not differentially expressed genes in data set three. Clusters 9 and 10 (in light and dark blue) group up-regulated genes in data set one, slightly up- or down-regulated genes in data set two, and not differentially expressed or down-regulated genes in data set three. The common set of up-regulated genes (17) comprises clusters 1, 2, and 3. These 17 genes (**Table 2**) are good candidates to be direct targets of *ORE1* as they are rapidly induced after *ORE1* overexpression (two hours) and are expressed in elevated levels at later time points (five hours) and in mesophyll cell protoplasts transiently overexpressing *ORE1* for six hours. From 17 up-regulated genes, 14 are senescence associated genes (SAGs) (Buchanan-Wollaston *et al.*, 2005; Parlitz *et al.*, 2011; Van Der Graaff *et al.*, 2006; Balazadeh *et al.*, 2008a; Breeze *et al.*, 2011). We aimed to determine the role of other NACs within the *ORE1* regulon and included *VNI2* (*ANAC083*) and *ORE1* (*ANAC092*) to complete our set of putative *ORE1* direct targets. *VNI2* is one of the six TFs that were up-regulated at later time points (after five hours EST induction) as we described before, and based on published data (Breeze *et al.*, 2011), we decided to test a possible auto-regulation of *ORE1*; therefore, we also include *ORE1* itself in our analyses (**Table 2**).

Table 2. Common set of up-regulated genes upon *ORE1* overexpression. Expression is given as Log2 Fch (fold change). Data represent the mean of three biological replicates for *ORE1-IOE-5* hours and two biological replicates for the *ORE1-IOE-2* hours datasets and transfected protoplast (six hours). Bold letters indicate the subset of selected putative genes to prove direct interaction with *ORE1*.

* Senescence up-regulated genes (Buchanan-Wollaston *et al.*, 2005; Parlitz *et al.*, 2011, Van Der Graaff *et al.*, 2006; Balazadeh *et al.*, 2008a; Breeze *et al.*, 2011).

In an attempt to characterize particular pathways that are over-represented in the set of differentially expressed genes, we classified the genes into functional categories using PageMan (Usadel *et al.*, 2006). Over-representation was assessed using the Wilcoxon rank sum test. We selected the set of commonly up-regulated genes (17 genes, presented in **Table 2**). Due to the fact that we could not identify a set of commonly down-regulated genes, we assayed the over-represented functional categories in down-regulated genes of each dataset and produced a consolidated table of over-represented functional categories in all three data sets. Over-representation is assayed by comparing the categories in the set under analysis with the represented functional categories of the whole Affymetrix ATH1 array.

Significantly over-represented categories in the set of commonly up-regulated genes involved “lipid metabolism and degradation,” “secondary metabolism,” “stress” (particularly “abiotic stress”), “RNA processing” (particularly “ribonucleases”), “DNA synthesis and chromatin structure,” “protein, posttranscriptional modification, and degradation,” and “signaling” (particularly “receptor kinases”) (**Table 3a**). Significantly over-represented functional categories in the set of down-regulated genes included “RNA regulation of transcription,” “lipid metabolism and degradation,” “stress” including both, abiotic and biotic, “secondary metabolism” (particularly “phenylpropanoids”), “hormone metabolism,” “redox,” and “transport.” In the case of over-represented categories in down-regulated genes, the *P*-values are not given since for each dataset we obtained a *p*-value. Nonetheless, in all cases, the differences observed are statistically significant (**Table 3b**).

Table 3. Significantly over-represented functional categories in up- or down-regulated genes after six hours constitutive overexpression of ORE1 (35S:ORE1/6 hours cotransfected protoplasts) relative to the categories represented by the ATH1 array. (a) Up- and (b) down-regulated categories found using the Wilcoxon statistical test.

Functional Category P-value

a) Up-regulated classes

Lipid metabolism, degradation	7, 92E-04
Secondary metabolism	7, 92E-04
Stress.abiotic	7, 92E-04
RNA.processing, ribonucleases	7, 92E-04
DNA Synthesis, Chromatin structure	7,92E-04
Protein. posttranslational modification, degradation	7,92E-04
Signaling.receptor kinases	7,92E-04
Development unspecified	4,15E-10

b) Down-regulated classes

RNA regulation of transcription
Lipid metabolism, degradation
Stress, biotic, abiotic
Protein
Development unspecified
Secondary metabolism, phenylpropanoids
Hormone metabolism
Redox
Misc
Transport

4.2.2. Characterization of the ORE1 binding site and its occurrence in putative target genes

The group of genes that are direct targets of a transcription factor can be identified among early responsive genes by screening for the presence of its binding site (BS). Therefore, the characterization of the sequences bound by a transcription factor is an essential step in the identification of true targets. Olsen *et al.* (2005) reported the binding site of ORE1 as TTAGGACGTGATCATAG. The binding site of other NAC TFs has been characterized by the DNA-binding-protein-CELD method (DBP-CELD). Xue *et al.* (2005) reported that sequences bound by NAC TFs are rather long, including two consensus motifs separated by a spacer that is a few bp long (Balazadeh *et al.*, 2011; Wu *et al.*, 2012; Xue 2005). To deduce the BS of ORE1, our collaboration partner, Dr. Gang-Ping Xue, performed a binding site selection assay using a fusion protein consisting of a translational fusion of the ORE1 cDNA to a 6-His-tagged cellulase D (CELD), which serves for the affinity purification of the ORE1-DNA complex (Xue, 2005) (Fig. 11.A, C-D). As shown in Figure 11.B, positive clones carrying the *ORE1-CELD* construct were identified by a light red halo around the clones growing on a medium containing CMC (carboxymethyl cellulose). The halo is produced by the hydrolysis of cellulose and is visible after staining with a Congo-Red solution. A detailed description of the assay is given in experimental procedures section 4.4.4.

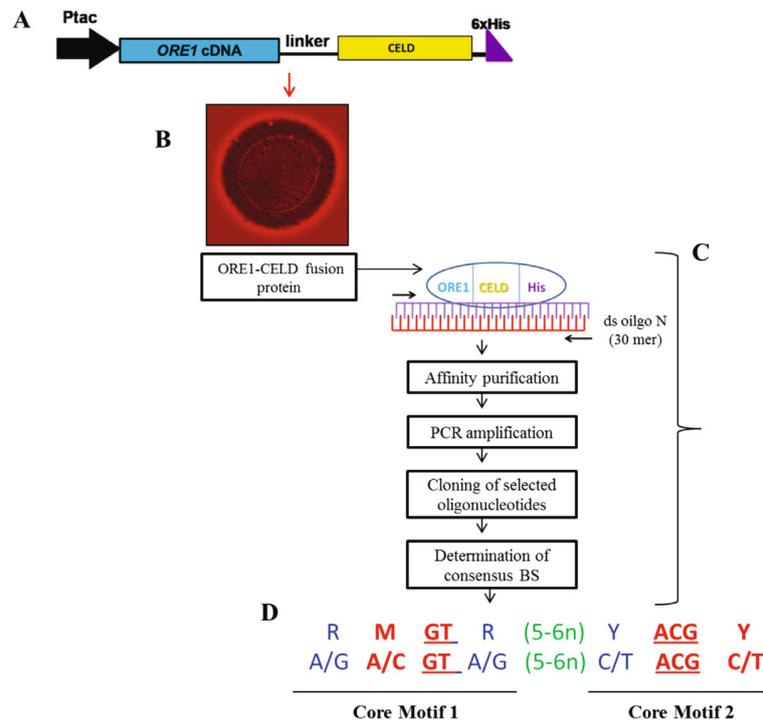

Figure 11. ORE1-BS selection assay. (A) Schematic representation of the *ORE1-CELD* construct. (B) *E. coli* colony expressing ORE1-CELD; bacteria were plated in sterile LB medium supplemented with Carboxymethyl-Cellulose (CMC, sodium salt). Positive colonies are detected after staining with a clear halo due to the positive cellulase activity. (C) Schematic representation of the CELD method. (D) ORE1 has high affinity to a target DNA where two core motifs, (RMGTR) and (YACGY), are spaced by 5-6 bp.

It has been shown that NAC TFs require more stringent binding sequences, not just the conserved core motif. Previously, we had reported RCGTR(4-5n)RYACGCAA as the consensus sequence recognized by ORS1/ANAC059 (Balazadeh *et al.*, 2011). According to Ooka *et al.* (2003), *ORS1* and *ORE1* are closely related proteins and represent paralogous in *Arabidopsis*. Within their NAM domains, they share an overall amino acid identity of 94% and a sequence identity of around 41% at the C-terminal region. Considering such high similarity between the NAM domains, we hypothesized that ORE1 binding specificity may be similar to that of ORS1. We tested the binding affinity of ORE1 with the ORS1-BS and with different oligonucleotides with small variations (substitutions or deletions/additions). As shown in **Table 4**, ORE1 binding specificity to ORS1-BSs (ORS1) is very high (1.00). Nevertheless, a transversion in the first motif (ORS1m2) from C to A causes only a slight reduction in binding from 1.00 to 0.93, while a transition in the second binding motif (ORS1m1) from G to A results in a greater reduction in binding affinity from 1.00 to 0.63. To test the influence of the spacer between the first and second motifs, deletions and additions analyses were carried out (motifs ORE1m5 to ORE1m7). It can be seen that a spacer of either 4 bp or 7 bp causes a drastic reduction in binding affinity (from 1.00 to 0.17 and 0.33, respectively). These data allowed us to conclude that ORE1 preferentially binds to the consensus sequence RMGTR(5-6n)YACGY (**Fig. 11.D**).

Table 4. ORE1 binding sequence determined by comparison with the ORS1-BS. Tested oligonucleotides are in the first column. Grey shadowing indicates the first core motif of ORE-BS, and red coloring indicates the spacer. Blue indicates the second core motif of ORE1-BS. Transitions are underlined in each case.

Selected oligonucleotides			
Synthetic oligos	Sequence		ORE1
ORS1	CGGGGTT ACGTA	CGGCA CACGCAACCGTGC	1.00 ± 0.09
Mutated oligos (substitutions)			
ORS1m1	CGGGGTT ACGTA	CGGCA CACACAACCGTGC	0.63 ± 0.01
ORS1m2	CGGGGTT AAGTA	CGGCA CACGCAACCGTGC	0.93 ± 0.11
ORS1m3	CGGGGTT GCGTA	CGGCA CACGCAACCGTGC	1.13 ± 0.02

ORS1m7	CGGGGTT ACGTA	CTCGGCA CACGCAACCGTGC	0.33 ± 0.01

Values are means ± SD of three assays.

4.2.3. ORE1 activates its putative target genes *in vivo*

We performed a series of *in vivo* and *in vitro* analyses to test whether ORE1 can directly bind and activate the promoters of its putative target genes. First, we searched *in silico* for the

presence of the ORE1 binding site as determined by the DBP-CELD method (section 4.2.2) in the promoter regions of *BFN1* (1084 bp), *VNI2* (1571 bp), *RNS3* (1062 bp), *ORE1* (1281 bp), *SINA1* (1018 bp), and *SAG29* (831 bp) (sequences refer to up-stream of the start codon ATG). The program fuzznuc from EMBOSS was used to search for the presence of the complete or partial ORE1-BS that covers at least the first core motif (<http://helixweb.nih.gov/emboss/html/fuzznuc.html>) (Rice *et al.*, 2000). We identified 11 putative binding sites in *BFN1*, 19 in *VNI2*, nine in *RNS3*, eight in *ORE1*, 16 in *SINA1*, and 13 in *SAG29*. Notably, exclusively up-stream sequence of *VNI2* exhibited a putative ORE1-BS spanning the whole ORE1-BS RMGTR(5n)YACGC. This binding site corresponds to the sequence GAGTATGGTTTACGC and is located 164 bp up-stream of the ATG. *BFN1* contains the second longest version of the ORE1-BS with a transversion in the second motif (T instead of A in the twelve position) the sequence is ACGTATGAGACTCGC and is located 196 bp up-stream of the ATG (Annex 2).

To test whether ORE1 activates the promoter regions of its putative target genes *in vivo*, we performed a series of transactivation assays. The promoter regions of the putative target genes linked to the firefly luciferase reporter (*BFN1-LUC*, *VNI2-LUC*, *RNS3-LUC*, *SAG29-LUC*, *SINA1-LUC*, and *ORE1-LUC*) were co-transfected into *Arabidopsis* mesophyll protoplasts in the presence or absence of ORE1 fused to the Cauliflower Mosaic Virus (CaMV) 35S promoter (*35S:ORE1*) (Balazadeh *et al.*, 2010a) by PEG-mediated transformation (see Experimental Procedures, section 4.4.8). As shown in Figure 12, luciferase activity was significantly higher if the promoters of *BFN1*, *VNI2*, and *RNS3* were co-transfected with *35S:ORE1*, indicating that ORE1 transactivates the expression of these targets in mesophyll cell protoplasts. Promoter activity of *SAG29*, *SINA1*, and *ORE1* was not significantly different from basal expression; therefore, we concluded that these genes might not be direct targets of ORE1 (Fig. 12).

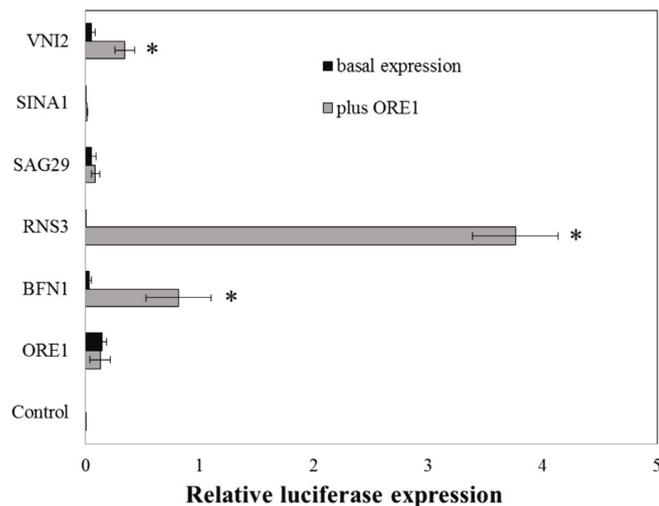

Figure 12. Protoplast transactivation of ORE1 and promoter regions of its targets. *Promoter-LUC* constructs were co-transfected into mesophyll protoplast with *35:RLuc* and with/without *35S:ORE1*. Luciferase activities were determined with the Dual Luciferase Reporter Assay System (Promega) 24 hours after transfection. Transfections were conducted in triplicate, and repeated once with a separate set of plants. Luciferase activities were normalized to corresponding Renilla luciferase activities (**P* value<0,05).

4.2.4. ORE1 binds to its putative target genes *in vitro*

Regulation of gene expression is in part mediated through the direct interaction of transcription factors with their consensus motifs located in the promoter of targets. In order to investigate the physical interaction of ORE1 with promoter regions of its putative target genes, we performed electrophoretic mobility shift assays (EMSAs). We designed primers by (**Annex 1**) flanking one of the ORE1-BS identified by the program fuzznuc (except for the gene *SAG29*) (**Fig. 13.A**). In our analysis, we included a primer designed for *SIN1A1*, although we found that *in vivo* this promoter is not significantly transactivated by ORE1 overexpression (**section 4.2.3**). We selected the longest and perfect binding site of *VNI2* and *BFNI* genes, and we selected *RNS3* and *SIN1A1* oligos by searching for a sequence containing the invariable core for ORE1 (ACGTA) and tested in CELD method (**section 4.2.2**). As a positive control, we used the sequence that showed the highest binding affinity in the CELD experiment: ORS1 synthetic oligo 5'-CGGGGTACGTACGGCACACGCAACCGTGC-3' (**Table 4**). Recombinant ORE1 protein fused to glutathione S-transferase (GST-ORE1) was incubated with 5'-DY682-labeled 40-bp double-stranded DNA fragments containing the different ORE1-BSs. GST-ORE1 was able to bind to all tested promoter fragments, including promoters that were not effective in the transactivation assays. All probes contained the same concentration of ORE1 protein and oligonucleotides. Thus, we assume that differences in band intensity are related to differences in binding affinity that may reflect the effect of the presence of the two core motifs of ORE1-BS. As shown in **Figure 13.B**, GST-ORE1 protein complexes migrate slower than the free DNA due to the interaction of ORE1 with its targets. ORE1 exhibited the strongest affinity to the *VNI2* promoter fragment in comparison to all other promoter-fragments tested. We attribute this strong affinity to the presence of a complete and perfect version (15 nucleotides) of the ORE1-BS in the *VNI2* promoter fragment. In the cases where the fragments span only the first core motif, like for *RNS3*, or only up to the first nucleotide of the second core motif, like in *SIN1A1*, the binding affinity was strongly reduced. Nevertheless, in the case of *BFNI*, the promoter fragment contained 15 nucleotides of the ORE1-BS and exhibited a low binding affinity. The *BFNI* promoter fragment contained a transversion in the second core motif of ORE1-BS (see above **section 4.2.3**). Therefore, we concluded that conservation of the first and second motif is essential to preserve ORE1 binding affinity. Binding affinity was significantly reduced if unlabeled promoter fragments were added in excess (competitor). The competition was dose-dependent, and no mobility shift was detected if the competitor was added in excess, indicating specific binding of ORE1 (**Fig. 13.B**).

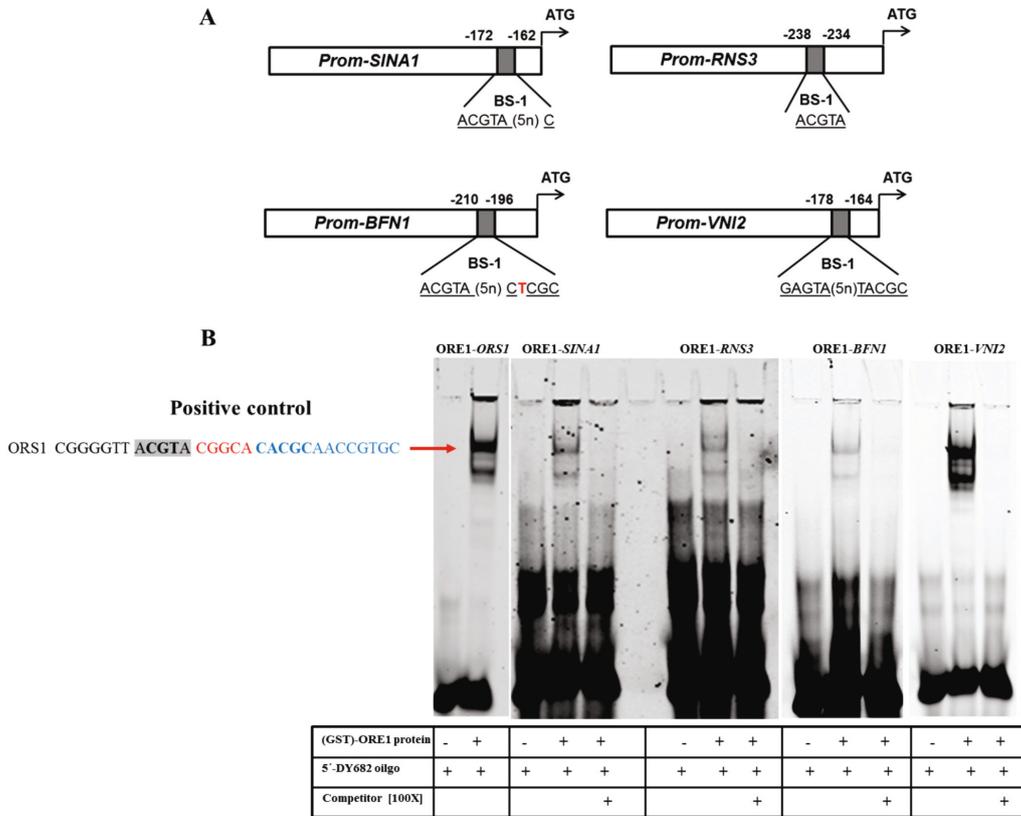

Figure 13. ORE1 binding activity *in vitro* by EMSA. (A) Schematic representation of 5'-DY682-labeled 40-bp DNA fragments **(B)** Electrophoretic mobility shift assays (EMSAs). Positive shift for all tested ORE1-putative-target genes in the presence of GST-ORE1 protein is indicated by a red arrow. Free DNA-oligos are seen at the bottom of the gel.

4.3. Conclusions

The transcriptome analyses provided important information about early regulated genes upon overexpression of ORE1. We identified a set of 17 commonly up-regulated genes that are highly and rapidly induced upon ORE1 overexpression. In contrast, we did not identify commonly down-regulated genes, and therefore, propose that ORE1 functions as a transcriptional activator like many other NAC TFs. The analysis for over-represented functional categories among the genes up- or down-regulated revealed that up-regulated genes are associated primarily with the degradation of macromolecules and signaling. We designed a list of six up-regulated genes to test if they are direct targets (*BFN1*, *VNI2*, *RNS3*, *ORE1*, *SINA1*, and *SAG29*). All the genes selected are known senescence-associated genes (SAGs), and two of them encode NAC TFs (Buchanan-Wollaston *et al.*, 2005; Balazadeh *et al.*, 2008a,b; Breeze *et al.*, 2011). We have characterized ORE1-BS as RMGTR(5-6n)YACGY and found that all selected targets contained different versions of ORE1-BSs in their promoters. ORE1 was able to bind to all of them *in vitro* (except for *SAG29* that was not tested). Additionally, *BFN1*, *VNI2*, and *RNS3* were significantly transactivated by ORE1 in

mesophyll cell protoplasts from *Arabidopsis*. Our results provide convincing evidence that supports *BFN1*, *VNI2* and *RNS3* as direct targets down-stream of ORE1. Further analyses are required to elucidate the biological relevance of these targets in the context of natural and induced-senescence.

4.4. Experimental procedures

4.4.1. General

Standard molecular techniques were performed as described in **Chapter 2, section 2.4.1**.

4.4.2. Plant material

The plant material and growth conditions used were similar to those described in **Chapter 2, section 2.4.2**.

4.4.3. Plant transformation

Arabidopsis transformation was performed as described in **Chapter 2, section 2.4.4**.

4.4.4. Constructs

Description of the overexpressor construct (**35S:ORE1**) was given in Balazadeh *et al.* (2010a).

Promoter-LUC constructs: promoter regions spanning 1.5 kb up-stream of the translation start codon ATG of *VNI2*, *BFN1*, *RNS3*, *ORE1*, *SIN1* and *RNS3* were amplified from genomic DNA by PCR using an Advantage HF 2 PCR Kit (Clontech) with gene-specific forward and reverse primers (**Annex 1**). Promoter fragments were subcloned into a pENTR-D-TOPO vector (Invitrogen, www.invitrogen.com) to generate individual entry vectors. The entry vectors were then recombined into the Gateway destination vector *p2GWL7.0* which is a recombination of the gateway vectors *pBGWL7.0* (transcription reporter vector) (Karimi *et al.*, 2002) and *p2GW7.0* (overexpression vector) (Licausi *et al.*, 2011) using the LR reaction mix II (Invitrogen) to obtain the final *BFN1-LUC*, *VNI2-LUC*, *RNS3-LUC*, *ORE1-LUC*, *SIN1-LUC*, and *SAG29-LUC* reporter vectors.

ORE1-CELD: *ORE1* cDNA was amplified by PCR from leaf cDNA with forward (116) and reverse (117) primers (**Annex 1**). The amplified fragment was inserted into pCR2.1-TOPO and then cloned via *NheI* and *BamHI* sites into plasmid pTacLCELD6XHis (Xue, 2005) to create an *ORE1-CELD* in-frame fusion construct (pTacORE1LCELD6XHis).

4.4.5. Transient expression of *ORE1* in protoplasts for transcriptome profiling

The protoplast preparation protocol was adapted from Sheen (2002). *Arabidopsis* mesophyll cell protoplasts were isolated from leaves (the second and/or third/fourth pair) of 5-week-old Col-0 (CS60000) plants grown on soil under long-day (16 hours light/8 hours dark) conditions. Leaves were placed in enzyme solution (1% cellulase R10, 0.3% macerozyme R10 (Yakult Honsha, Tokyo, Japan), 0.4 M mannitol, 20 mM KCl, 10 mM CaCl₂, 20 mM MES, 0.1% BSA (Sigma A-6793), pH 5.7) for 8.5 hours. Protoplasts were collected and kept on ice in W5 medium (154 mM NaCl, 125 mM CaCl₂, 5 mM KCl, 2 mM MES, pH 5.7) for 13 hours in the growth cabinet. Protoplasts were transferred to MMG solution (0.4 M mannitol, 15 mM MgCl₂, 4 mM MES pH 5.7), and subjected to PEG transfection. To 2.12×10^6 protoplasts, a total of 250 µg plasmid DNA was added followed by 30 minutes of incubation in 1 vol. of PEG solution (40% PEG 3500, 3 mL H₂O, 0.2 M mannitol, 0.1 M CaCl₂). After transfection, the samples were diluted with 2 vol. of W5 solution and collected by centrifugation at 100 g for two minutes. Protoplasts were then resuspended in 4 mL WI medium (0.5 M mannitol, 20 mM KCl, 4 mM MES, pH 5.7), transferred to 5 cm Petri dishes pre-coated with 5% calf serum, and incubated for 6 hours in the growth cabinet. After the incubation, protoplasts were collected, and 100 - 200 mg aliquots were flash-frozen in liquid nitrogen for subsequent RNA isolation and expression profiling.

4.4.6. Gene expression analysis by microarray

Three micrograms of quality-checked total RNA obtained from leaves of two and three biological replicates of *IOE-ORE1* and wild type lines, respectively (two hours and five hours after 10 µM estradiol treatment), and two biological replicates of the mesophyll cell protoplasts transiently overexpressing *35S:ORE1*, were processed for use in Affymetrix GeneChip hybridisations (GeneChip® *Arabidopsis* ATH1 array) as described (Redman *et al.*, 2004). RNA was obtained from *IOE-ORE1* and wild type 15-day-old seedlings grown in half MS (Murashige and Skoog, 1962) media with the selective antibiotic hygromycin (as described in **Chapter 2**). Seedlings were transferred from solid to liquid MS media one day before treatment to minimize secondary effects by stress. Seedlings of *ORE1-IOE* and wild type were treated/non treated with EST and, immediately after, whole seedlings were frozen in liquid nitrogen (N) for RNA extraction. ATH1 arrays allow the analysis of around 24.000 *Arabidopsis* genes. Labeling, hybridization, washing, staining, and scanning procedures were performed by Affymetrix Authorized Service Provider (ATLAS Biolabs, Berlin, Germany) as described in the Affymetrix technical manual. Raw data (CEL files) obtained from RNA hybridization experiments were normalized with the affyPLM package from the Bioconductor software project (Gentleman *et al.*, 2004) using the GCRMA that uses GC content of probes in normalization with RMA (Robust Multiple array Average) and gives one value for each probe set instead of keeping probe level information (Wu and Irizarry, 2004). The heat map was produced using the software gplots from R. The Log₂FC

results for the 54 probe sets up-regulated in the ATH1 Affymetrix after two hours inducible overexpression of ORE1 were clustered together with the corresponding results after five hours inducible overexpression and 6 hours constitutive overexpression. The hierarchical clustering was performed using Euclidian-distance as the method of pairwise distance calculation. The dendrograms group treatments (columns) and probe sets (rows) according to their similarity (Warnes *et al.*, 2009)

4.4.7. ORE1 binding affinity to ORS1 perfect and mutated binding sites

This work was performed in collaboration with Dr. Gang-Ping Xue, CSIRO Plant Industry, St. Lucia, Australia. The DNA-binding activity of ORE1-CELD protein was measured using methylumbelliferyl β -D-cellobioside (MUC) as substrate as described in Xue (2002). DNA-binding assays with a biotin-labeled single-stranded oligonucleotide, or a biotin-labeled double-stranded oligonucleotide without a target binding site, were used as controls.

4.4.8. Dual-luciferase assay

Dual-luciferase assay was performed as described in **Chapter 2, section 2.4.7**. Promoter regions of ORE1 putative genes were used as reporter plasmids: a 1.0 kb up-stream of the ATG was amplified from genomic *Arabidopsis* ecotype Col-0 DNA to generate reporter final constructs: *BFN1-LUC*, *VNI2-LUC*, *RNS3-LUC*, *SAG29-LUC*, *SIN1-LUC*, and *ORE1-LUC* (described in **section 4.4.4**). As an effector plasmid, a *35S:ORE1* construct was used. Normalization of data was performed based on relative luciferase of the *35S:RLuc* normalization vector (Licausi *et al.*, 2011).

4.4.9. EMSA

For protein expression and purification, the *ORE1* cDNA was recombined in vitro into the Gateway vector pDEST24 (Invitrogen) encoding a C-terminal GST-tag, and transformed into the *E. coli* expression strain BL21 (DE3) pLysS (Agilent Technologies). The pDEST15 vector (Invitrogen) was used for expression and purification of GST alone. Expression of GST and ORE1-GST fusion proteins was carried out in 400-smL cultures and induced at 30°C by 1 mM isopropyl thio- β -D-galactoside for 3 hours. Harvested cells were lysed in 20 mL GST lysis buffer (20 mM sodium phosphate buffer, pH7.3, 150 mM NaCl, 1 mM EDTA, 0.2% Triton X-100, 1 mM dithiothreitol, 1 mM phenylmethanesulfonyl fluoride, 10 μ g/mL aprotinin, 10 μ g/mL leupeptin, 2 mM benzamidin) and ultrasound treatment. According to the instructions of the manufacturer, the supernatant of ultracentrifuged samples was used for affinity purification with 70 mg of pre-equilibrated glutathione-agarose beads (Sigma-Aldrich). Aliquots of the elution fractions were analyzed by SDS-PAGE and Coomassie staining. One-mL fractions containing the purified proteins were pooled and dialyzed against PBS buffer (20 mM sodium phosphate buffer, pH7.4 and 150 mM NaCl). Concentrations

of purified proteins were determined by SDS-PAGE and Coomassie staining using BSA standards. 5-DY682-labeled DNA fragments were obtained from MWG (Ebersberg, Germany). Sequences of labeled DNA fragments, unlabeled competitors, and mutated fragments are given in **Annex 1**. Annealing was performed by heating the primers to 100°C followed by slow cooling to room temperature (RT). Binding reaction was performed at RT for 20 minutes as described in the Odyssey Infrared EMSA kit instruction manual. DNA-protein complexes were separated on 6% retardation gel while DY682 signal was detected using the Odyssey Infrared Imaging System for LI-COR Biosciences.

Contributions

Dr. Gang Ping Xue performed the CELD experiment. Dr. Wolfgang Dröge Laser performed transient overexpression of *ORE1* in *Arabidopsis* protoplasts (*35S:ORE1*/6 hours). Dr. Hakan Dortay and Katharina Schulz produced recombinant ORE1-GST protein.

Chapter 5

Expression of *BIFUNCTIONAL NUCLEASE1 (BFN1)* during senescence in *Arabidopsis* is regulated by the NAC transcription factor *ORE1/ANAC092/AtNAC2*

A version of this work will be submitted to *The Plant Journal*

5.1. Introduction

Senescence is a regulated process associated with the final developmental stages in plants. It can also be triggered by abiotic and biotic stresses. Several of the more than 20 senescence up-regulated NAC TFs in *Arabidopsis thaliana* have been shown to regulate senescence, including (among others) *AtNAP/ANAC029* (Guo and Gan, 2006), *ORE1/ANAC092/AtNAC2* (Balazadeh *et al.*, 2010a,b; Kim *et al.*, 2009), and *ORESAR1 SISTER1/ORS1/ANAC059* (Balazadeh *et al.*, 2011) which all promote senescence, and recently, the NAC factor *VASCULAR-RELATED NAC-DOMAIN (VND) INTERACTING2 (VNI2, ANAC083)* has been reported to integrate ABA signaling and leaf senescence (Yang *et al.*, 2011). *ORE1* has been shown to be a central regulator of senescence in *Arabidopsis thaliana* (Balazadeh *et al.*, 2010a,b; Breeze *et al.*, 2011). Despite the amount of available data, the exact mechanisms

that govern the onset and progression of senescence remain unknown at present, but direct interactions between this NAC TF (ORE1) and their target genes are clearly needed for this process. ORE1 has recently been shown to play a role in developmental and induced senescence as well as programmed cell death (PC) (Balazadeh *et al.*, 2010a,b; Kim *et al.*, 2009).

It was established that the *ore1-1* allele isolated from an EMS-mutagenized pool, and the *ore1-2* allele isolated from a population of fast neutron-mutagenized Col-0 seeds, conferring the delayed leaf senescence phenotype (Aeong Oh *et al.*, 1997; Kim *et al.*, 2009) as well as the *anac092-1* T-DNA insertion mutant. In contrast, *ORE1* overexpression strongly enhances senescence (Balazadeh *et al.*, 2010a). Kim *et al.* (2009) proposed a trifurcate feed-forward pathway involving *ORE1*, *microRNA164* (*miR164*), and *EIN2* (*ethylene insensitive 2*) ensuring highly robust regulation of leaf senescence and aging induced cell death. *ORE1* expression is positively regulated by *EIN2* but negatively by *miR164* with leaf age. *EIN2* functions as a negative regulator of *miR164* expression in an age-dependent manner. Age-dependent down-regulation of *miR164* leads to accumulation of *ORE1* expression. Despite clear evidence of *ORE1* as a key role in the regulation of leaf senescence, knowledge about the molecular mechanism(s) and gene network(s) through which *ORE1* exert its senescence regulatory function is still limited. We have previously described genes whose mRNA expression is rapidly induced upon *ORE1* induction (*ORE1* regulon), and are, therefore, candidates for being direct targets of *ORE1* (**Chapter 4**). Bioinformatics analysis and network modeling, based on high-resolution time-course profiles of gene expression during leaf development, predict genes whose expression is positively influenced by *ORE1* (Breeze *et al.*, 2011). *BFN1*, which is among the genes that are rapidly and positively regulated by *ORE1*, encodes a type I nuclease; it shares high amino acid sequence similarity to DSA6 nuclease, which is associated with petal senescence in daylilies (Panavas, 1999), and to *ZEN1* nuclease, which is associated with PCD in *Zinnia elegans* (Ito and Fukuda, 2002). *BFN1* expression was already enhanced by around fourfold two hours after EST treatment in *ORE1-IOE* lines. Its expression further increased to fortyfold within five hours of EST treatment. An extreme activation of *BFN1* expression (a thousandfold) was observed in the *35S:ORE1* six hours after protoplast transfection (**section 4.2.1**). *BFN1* expression has been shown to be specifically enhanced during leaf and stem senescence, as well as in the floral abscission zone and during developmental PCD (Breeze *et al.*, 2011; Buchanan-Wollaston *et al.*, 2005; Farage-Barhom *et al.*, 2011; Pérez-Amador *et al.*, 2000; Wagstaff *et al.*, 2009). Intracellular localization studies revealed that at later stages of senescence, *BFN1*-GFP is localized with fragmented nuclei in membrane coated vesicles, suggesting the role for *BFN1* in regulated nucleic acid degradation occurs during senescence and developmental PCD (Farage-Barhom *et al.*, 2011). In **Chapter 4** we obtained strong evidence that support a possible direct interaction of *BFN1* by *ORE1*. Here, we demonstrated that *ORE1* specifically activates the *BFN1* promoter. *BFN1* and *ORE1* tissue-specific expression show largely overlapping patterns, reaffirming the idea of co-expression. We proved that binding of *ORE1*

to *BFNI* promoter is highly specific, and single mutations in ORE-BS that are present in the *BFNI* promoter hardly affect binding activity *in vivo*. Moreover, we revealed that senescence-enhanced expression of *BFNI* is abolished in the *anac092-1* T-DNA insertion mutant, indicating *ORE1* as a major regulator of *BFNI* expression during senescence. Our results give convincing data that supports *BFNI* as a direct target down-stream of *ORE1*.

5.2. Results

5.2.1. Overlapping patterns of transcriptional activities of *BFNI* and *ORE1* promoters

The elevated expression of *BFNI* in the cells and transgenic plants overexpressing *ORE1* indicated that the NAC TF acts as an up-stream positive regulator of *BFNI*. We, therefore, analyzed the extent of co-expression of both genes in *Arabidopsis* plants. Gene expression profiling data revealed induction of both *BFNI* and *ORE1* during leaf and pistil developmental senescence (Breeze *et al.*, 2011; Buchanan-Wollaston *et al.*, 2005; Farage-Barhom *et al.*, 2011; Pérez-Amador *et al.*, 2000; Wagstaff *et al.*, 2009) and during dark- and salt-induced senescence (Balazadeh *et al.*, 2010b; Buchanan-Wollaston *et al.*, 2005). Moreover, expression of both genes was highly induced upon 180 minutes ABA treatment in 7-day-old seedlings (*Arabidopsis* Hormone Database) (Jiang *et al.*, 2011) and significantly reduced in the *ein2* mutant that lacks a major component of the ethylene signaling pathway (Buchanan-Wollaston *et al.*, 2005). To investigate the extent of overlapping promoter activities during senescence, we looked at *ORE1* and *BFNI* promoter activities using promoter- β -glucuronidase (*GUS*) reporter lines. Transgenic *Arabidopsis* lines expressing the *GUS* reporter gene, driven by the 2.3 kb *BFNI* up-stream region (Farage-Barhom *et al.*, 2008) or the 1.5 kb *ORE1* up-stream region (Balazadeh *et al.*, 2010a), were analyzed side by side to identify unique and overlapping expression patterns of both genes. In general, expression patterns of both promoter fusions were highly similar in leaves and floral organs at different developmental stages, while expression was largely absent in young tissues, consistent with the function of both genes during senescence (**Fig. 14**). Examination of *GUS* expression in 15-day-old seedlings revealed high *BFNI* and *ORE1* expression in cotyledons as well as in the tip regions of leaves. *BFNI* expression was faint in roots (**Fig. 14.a**) compared to *ORE1* expression in the same tissues (**Fig. 14.f**). In both *BFNI* and *ORE1* plants 40 days after sowing (DAS), *GUS* activity was specifically detected in tip and margin regions of senescence leaves (**Fig. 14.b,g**). *GUS* activity was prominent in the stigma, mature anthers, and sepals of mature/fully opened flowers (flower stage 13/14 as classified by Ferrandiz *et al.* (1999) (**Fig. 14.d,i and c,h**). Expression in mature siliques was detectable in abscission zones (AZ) at the bottom and upper parts of the valve margins for both *Prom-ORE1:GUS* and *Prom-BFNI:GUS* (**Fig. 14.e,j**). We also observed *GUS* expression in *Prom-ORE1:GUS* lines in the replum of mature fruits and faintly in *Prom-BFNI:GUS* (**Fig. 14.j**). Thus, our data largely demonstrated overlapping expression patterns for the NAC transcription factor *ORE1* and its direct down-stream target *BFNI*.

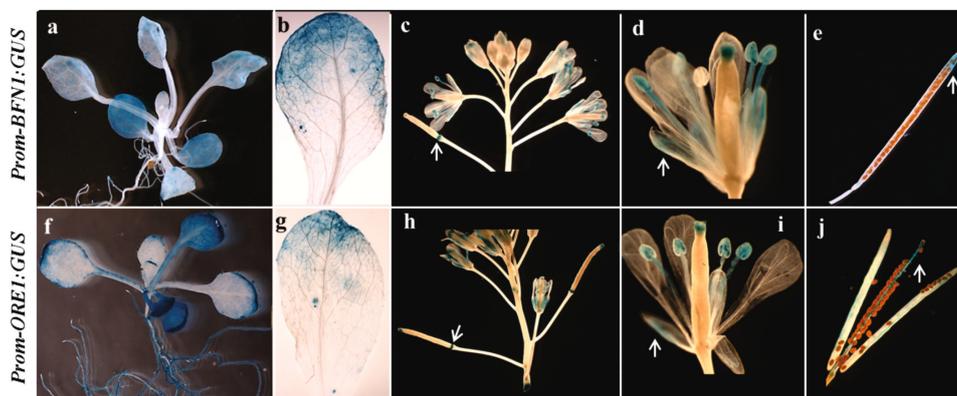

Figure 14. Histochemical GUS staining of *Prom-BFN1:GUS* and *Prom-ORE1:GUS* in *Arabidopsis*. Plants were transformed with *Prom-BFN1:GUS* (top) and *Prom-ORE1:GUS* (bottom): (a, f) *Arabidopsis* seedlings (15-day-old) exhibited strong GUS activity in cotyledons and tip regions of leaves. (b, g) *Arabidopsis* leaves (40 DAS) showed strong GUS activity in the tip and margin regions of leaves corresponding to the oldest tissues. (c, h) Bolting branch with young and old flowers. GUS was observed in mature/opened flowers. GUS activity was observed in the flower abscission zone (indicated by arrows). (d,i) close-up of mature/opened flowers (flower stage 13/14 as classified by Ferrandiz *et al.* (1999). Strong GUS activity on stigma and mature anthers was detected. GUS activity was faint in sepals (indicated by arrows). (e,j) close-up of mature siliques. GUS activity was detected in abscission zones (AZ) at the bottom and upper part of the siliques. In the case of *Prom-ORE1:GUS*, promoter activity was also detected in the replum (indicated by arrows) and along the aperture site of the valves.

5.2.2. Altered level of BFN1 protein in ORE1 transgenic plants

Nuclease I enzymes are involved in the degradation of RNA and single-stranded DNA during several plant growth and developmental processes, including senescence. BFN1 RNase and DNase nuclease activities were detected in activity gels at about 38 kDa using leaves from transgenic *Arabidopsis* plants overexpressing *BFN1*. Nuclease activity was almost undetectable when using roots and non-senescent leaves and stems. Furthermore, senescent flowers also exhibited enhanced nuclease activity. These results demonstrated that *BFN1* encodes a bifunctional nuclease capable of degrading RNA and DNA (Pérez-Amador *et al.*, 2000). To further confirm that *BFN1* expression is ORE1-dependent, we measured changes in BFN1 nuclease protein levels in plants overexpressing or lacking ORE1 protein. All protein was extracted from (i) estradiol (EST) treated and (ii) non-treated (15-day-old) *ORE1-IOE* seedlings after 24 hours of induction. In order to avoid artifacts due to the EST treatment, we analyzed BFN1 activity in *ORE1* overexpressor lines (*35S:ORE1*, lines 23 and 24) using protein extracts from leaves in which senescence was artificially induced. All leaves were at full senescence, as judged by complete yellowing of the tissue, and empty vector lines (E.V.) were used as controls. Additionally, BFN1 nuclease protein level was measured in the *anac092-1* T-DNA insertion mutant and wild type plants (30-DAS). Same position leaves (6 and 7) were detached and incubated in the dark until full senescence was obtained (after seven days in the wild type and nine days in the mutant). Proteins were extracted from the plant material described above and used for Western blot analysis using BFN1 antiserum.

The position of the senescence-induced BFN1 protein was clearly visible in the analysis, indicated by black arrows on the gels. The expression level of BFN1 nuclease protein was detected in *ORE1-IOE* seedlings upon treatment with EST (**Fig. 15.D**), whereas it was undetectable in untreated *ORE1-IOE* seedlings (**Fig. 15.C**). This result strongly supports that at earlier developmental stages, BFN1 expression is absent. Nevertheless, an increase in the ORE1 protein level after EST treatment is able to trigger the expression of BFN1, even in young plants like seedlings (**Fig. 15.D**). Interestingly, proteins extracted from inducible *ORE1* lines and constitutive *ORE1* overexpressors (**Fig. 15.D, G-H**) exhibited a substantial reduction in the amount of proteins compared to non-treated *ORE1-IOE* seedlings and wild type protein extracts; in particular, degradation of Rubisco LSU (ribulose biphosphate carboxylase/oxygenase large subunit) was evident, which is in accordance with the fact that overexpression of ORE1 triggers senescence and accelerates protein degradation. Rubisco protein is indicated by red arrows on the gel images. As expected, BFN1 nuclease protein was almost absent in senescent leaves of the *anac092-1* T-DNA insertion mutant compared to senescing leaf protein extract from wild type plants. As expected, the *anac092-1* T-DNA insertion mutant plants showed bands of Rubisco signal which is in accordance with the delay of senescence in these lines and the retardation of protein degradation (**Fig. 15.A-B**). Overall, our results confirm that *BFN1* expression is ORE1-dependent.

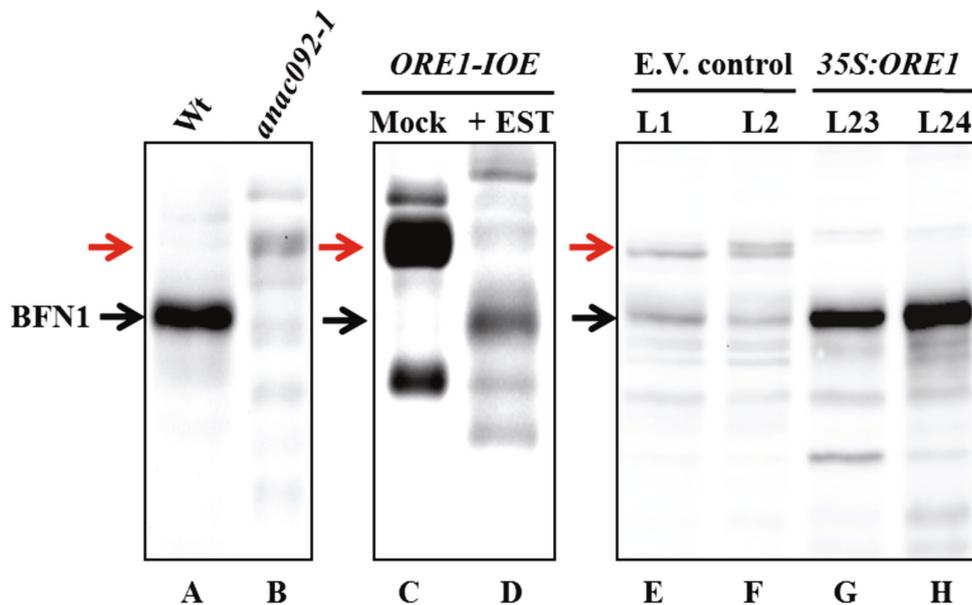

Figure 15. Altered level of BFN1 protein in *ORE1* transgenic plants detected by Western blot. In all blots, red arrows corresponds to Rubisco LSU (ribulose biphosphate carboxylase/oxygenase large subunit) and black arrows correspond to BFN1 protein. (A) Enhanced BFN1 protein level in wild type protein extract. (B) BFN1 protein is almost absent in *anac092-1* T-DNA insertion mutant. *anac092-1* T-DNA insertion mutant shows a considerable concentration of Rubisco LSU, indicating that protein degradation is almost absent. BFN1 protein level was absent in untreated inducible *ORE1* overexpression seedlings (C) compared to treated seedlings after 24 hours EST treatment (D). Lower levels of BFN1 protein were detected in pGreen empty vector lines (E.V.) control plants (E-F) compared to a markedly BFN1 protein level in 35S:*ORE1* overexpressor lines (L24 and L25) (G-H).

5.2.3. Senescence-specific expression of *BFN1* is *ORE1*-dependent

In order to test whether the senescence-induced expression of *BFN1* is dependent on the presence of functional *ORE1*, we tested *BFN1* expression in the *ore1-1* EMS mutant using plants from different developmental stages; plants were grown in soil and leaves were harvested from plants 12, 16, 20, 24, 28, 32, and 36 days after sowing. As shown in **Figure 16**, *BFN1* expression strongly increased with age in wild type plants; expression was sixtyfold higher in leaves of 28-day-old plants compared to leaves of 24-day-old plants. Expression of *BFN1* remained high and increased further at later time points (in 32- and 36-day-old plants), consistent with previous observations that *BFN1* is a senescence-associated gene (Farage-Barhom *et al.*, 2011; Pérez-Amador *et al.*, 2000; Wagstaff *et al.*, 2009). In contrast, the age-dependent increase of *BFN1* transcript abundance was completely abolished in leaves of the *ore1-1* EMS mutant. These data indicate that senescence-associated expression of *BFN1* is mainly, if not exclusively, regulated by *ORE1*. Considering the negative regulation of *ORE1* by *mir164abc* during leaf aging, we next tested *BFN1* transcript level in the *mir164abc* triple mutant at different leaf developmental stages (as described above). The difference in *BFN1* transcript between younger and older leaves was greater in *mir164abc* mutants than wild type plants (**Fig. 16.A**).

To further confirm that expression of *BFN1* is *ORE1*-dependent, we tested the expression of an exclusively senescence marker. *SAG12* mRNA expression was measured in the same plant material. As expected, *SAG12* expression increased with age in wild type plants with a maximum value at the later time point (36-day-old plant). In contrast to *BFN1* mRNA expression in *ore1-1* EMS mutant, *SAG12* increased with age following the same pattern as in wild type and *mir164abc* mutants. *SAG12* expression increased at a lower rate in the *ore1-1* EMS mutant than in wild type and *mir164abc* mutants, confirming that the absence of *ORE1* delays senescence. In the end, expression of *SAG12* was the same in all tested plants. These results confirm that all tested plants reach senescence in the latest time point (after 36 days after germination), and the absence of functional *ORE1* not only delays senescence but directly controls the expression of *BFN1* (**Fig. 16.B**).

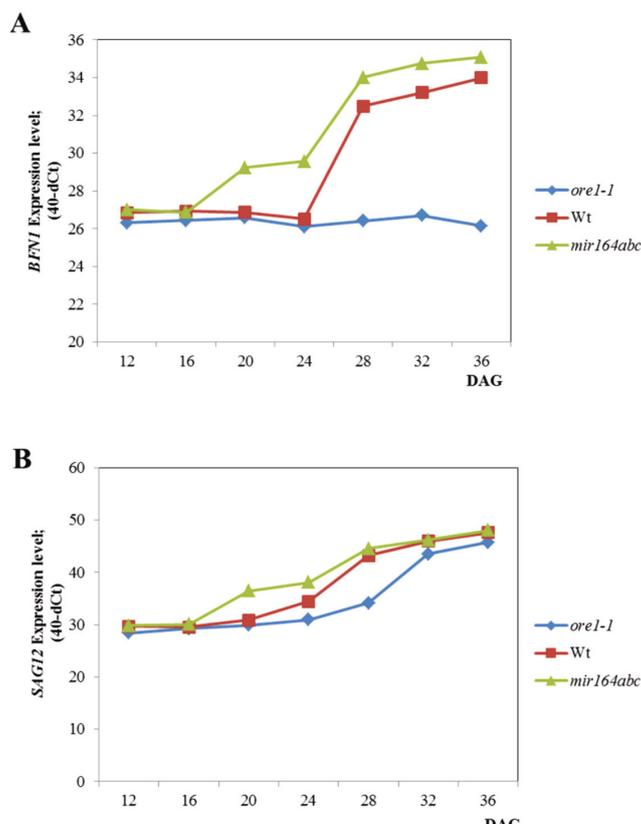

Figure 16. *BFN1* and *SAG12* expression in *ore1-1* EMS mutant, *mir164abc*, and wild type plants. (A) *BFN1* and (B) *SAG12* transcript levels in leaves of *ore1-1* EMS mutant, *mir164abc* mutant, and wild type *Arabidopsis* plants at different ages (12, 16, 20, 24, 28, 32, and 36 days after germination). Expression level was determined by qRT-PCR, and data are means of two biological replicates.

To further confirm ORE1-dependent expression of *BFN1* during senescence, we transformed the *anac092-1* T-DNA insertion mutant with the *Prom-BFN1:GUS* construct (Farage-Barhom *et al.*, 2008) and compared it to the expression patterns and GUS activity in wild type plants that were transformed using the same construct. To minimize the potential effect of the integration point, we analyzed more than 50 independent lines transformed with *Prom-BFN1:GUS*. The presence of the *GUS* gene in all lines was confirmed by PCR on genomic DNA (**Fig. 17.E**). Histochemical staining revealed strong reduction, and in most cases, absence of detectable *BFN1* promoter activity in the *anac092-1* T-DNA insertion mutant background compared to wild type (**Fig. 17.A-B**). Additionally, we quantitatively determined GUS activity using 4-methylumbelliferyl- β -D-glucuronide (4-MUG) as substrate in an assay and taking fully expanded juvenile leaves (from 20-day-old plants) and senescent leaves showing less than 50% yellowing (from 40-day-old plants) of *Prom-BFN1:GUS* transgenic lines. As shown in **Figure 17.F**, reporter gene activity was significantly reduced in *Prom-BFN1:GUS/anac092-1* T-DNA insertion mutant lines compared to *Prom-BFN1:GUS/wild type* plants. Reduced GUS activity was particularly pronounced in senescent leaves compared to young leaves.

These data confirm that ORE1 plays a central role as an up-stream transcriptional regulator of *BFNI*.

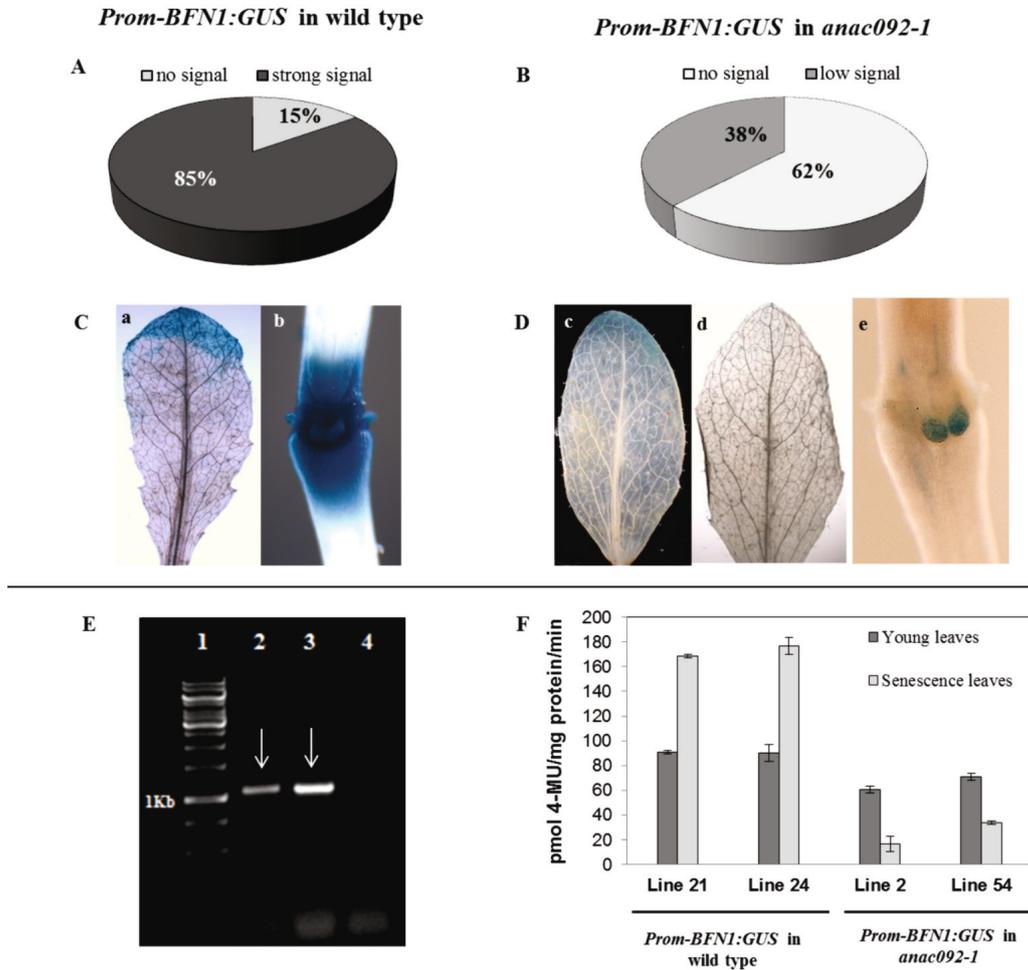

Figure 17. Expression patterns of *Prom-BFNI:GUS* in wild type (Col-0) (upper left panel) and *anac092-1* T-DNA insertion mutant (upper right panel) backgrounds. (A) Percentage of transgenic lines (*Prom-BFNI:GUS* in wild type background) with strong GUS activity (strong signal) compared to percentage of plants without GUS activity (no signal). (B) Percentage of transgenic lines (*Prom-BFNI:GUS* in *anac092-1* T-DNA insertion mutant background) that exhibited reduction (low signal) or absence of GUS activity (no signal). (C.a) Strong GUS activity in the tip region of an old leaf (line 24). (D.e) Faith GUS activity in the tip region of an old leaf (line 54). (D.d) Absence of GUS activity in tip region of an old leaf (line 2). (C.b–D.e) GUS activity within floral abscission zone (AZs) in the remaining cells for protective scar tissue and the region surrounded. The images displayed are representative of at least 30 plants examined for each line per experiment. **Bottom right panel:** (F) Quantitative GUS activity of *Prom-BFNI:GUS* measured by a MUG assay in fully expanded transgenic lines from young leaves (from 20-day-old plants) and senescent leaves (from 40-day-old plants); *Prom-BFNI:GUS* in wild type background (lines 21 and 24) and *Prom-BFNI:GUS* in *anac092-1* T-DNA insertion mutant background (lines 2 and 24). Data are the means of two biological and three technical replicates. **Bottom left panel:** (E) PCR analysis of 40-day-old *Prom-BFNI:GUS* transgenic plants. DNA was isolated and used as templates for GUS specific amplification. Lane 1 is DNA size marker. Lane 2 is PCR product of *Prom-BFNI:GUS* in wild type background (line 21). Lane 3 is PCR product of *Prom-BFNI:GUS* in *anac092-1* T-DNA insertion mutant line background (line 2; plants showed no GUS staining). Lane 4 is the negative control. White arrows indicate GUS-specific amplification, fragment size 1139 bp. The sequence of GUS-specific primers is given in **Annex 1**.

5.2.4. ORE1 binding activity to *BFN1* promoter is highly regulated by ORE1-binding site (BS)

Transient transactivation assays have been widely used as a powerful and rapid method to predict transcription factor direct target genes and elucidate functional *cis*-regulatory motifs within promoters of target genes (Licausi *et al.*, 2011; Park *et al.*, 2010; Yang *et al.*, 2011; Zhong *et al.*, 2010, Zhou *et al.*, 2009). In **section 4.2.3**, we established that ORE1 transactivates *BFN1*-promoter in mesophyll protoplast. Additionally, we determined that the *BFN1* promoter contains 11 different versions of the ORE1 binding site (BS), but only one corresponds to the longest version (ACGTATGAGACTCGC) that is 15 nucleotides long and contains one transition (“T” instead of “A”). This ORE1-BS is located 196 bp up-stream of the ATG and was named BS-1 for further analysis. We aimed to test if BS-1 is crucial for ORE1-mediated transactivation of the *BFN1* promoter. We compared the effect in the transcriptional activation of *BFN1* using three different *BFN1* promoters fused to luciferase (reporter gene): (i) 1084 bp up-stream of the start codon ATG and contained the original BS-1 (*BFN1-LUC*); (ii) a second version *BFN1-M-LUC* covered the same region but carried a substitution in the first core motif of BS-1 (“CGT” was substituted with “AAA”); and (iii) *BFN1-S-LUC* comprised truncated promoter (192 bp) that lacked all ORE1-BSs (binding sites) (**Fig. 18.A**). Our luciferase-based assay data demonstrate that the introduction of these substitutions in BS-1 significantly reduced the ORE1 mediated transactivation (**Fig. 18.B**). This data made us conclude that BS-1 regulated the direct interaction of ORE1 to *BFN1* promoter. However, the change in BS-1 did not lead to a complete abolishment of *BFN1* transactivation, indicating that other active binding sites in *BFN1* promoter mediated its transactivation. Analyses *in silico* indicated that *BFN1* promoter contains 11 ORE1-BS in the promoter which covers at least the complete first core motif (**Annex 2**). Thus, it is plausible to think that those ORE1-BS are active and able to transactivate *BFN1*. Indeed, the deletion of *BFN1* promoter to a 192 bp fragment resulted in further reduction of *BFN1* transactivation. Interestingly, *BFN1-S-LUC* transcriptional activity was still detectable at a higher level than basal activity. Therefore, we conclude that ORE1 is a major regulator of *BFN1* but might possess other active BSs that are able to lead transactivation of its promoter.

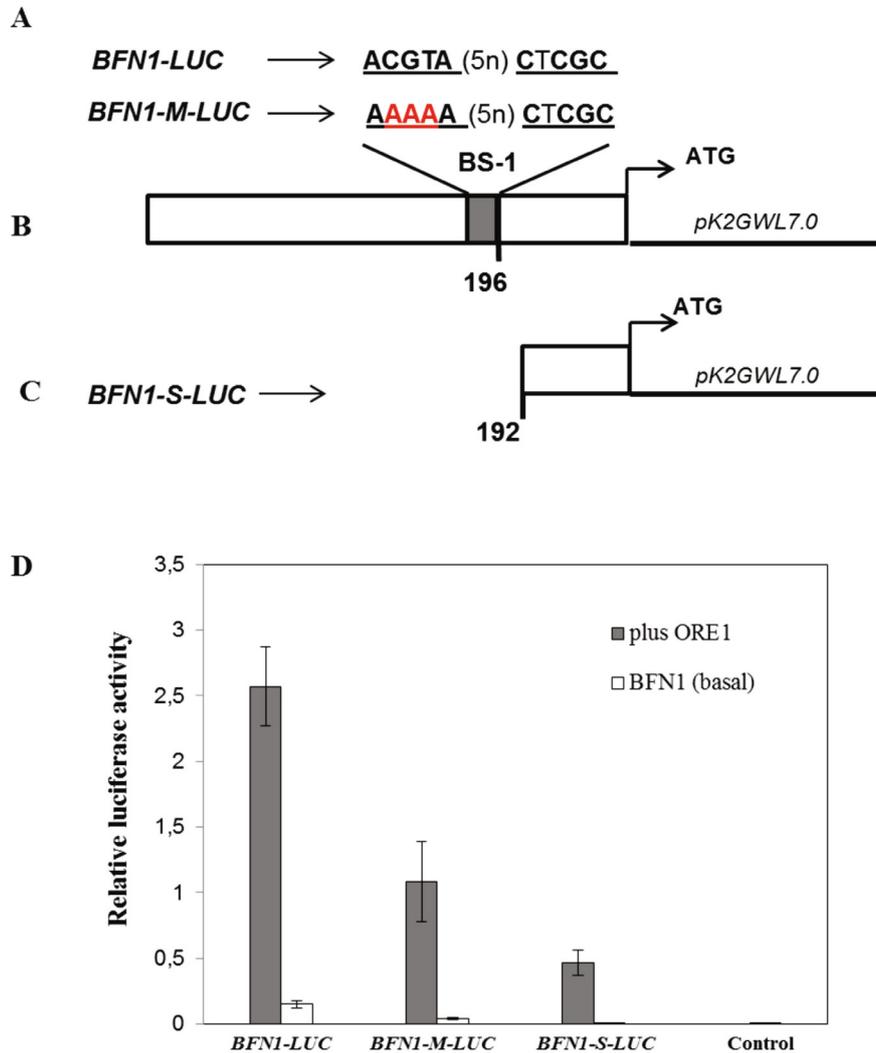

Figure 18. Transactivation of *BFN1* expression by ORE1 in *Arabidopsis* mesophyll protoplasts. Schematic representation of the constructs co-transfected in *Arabidopsis* mesophyll protoplast. (A) 1.0 kb promoter fused to luciferase (*BFN1-LUC*), (B) 1.0 kb promoter carrying substitutions (*BFN1-M-LUC*), and (C) 192 bp (*BFN1-S-LUC*) lack all ORE1-BSs. (D) Luciferase activity of each version of *BFN1* promoter in presence (plus ORE1) or absence (BFN1-basal) of *35S:ORE1*. Luciferase activity was determined using the Dual Luciferase Reporter Assay System (Promega) 24 hours after transfection. In all cases, normalization of data was performed using the CaMV *35S:Rluc* plasmid. Bars indicate the standard errors of three biological replicates.

5.3. Conclusions

We determined that ORE1 binds to the *BFN1* promoter *in vitro* and is able to transactivate the *BFN1* promoter *in vivo*. In this study, we show that *BFN1* and *ORE1* tissue-specific expression show largely over-lapping patterns, and *BFN1* expression is highly dependent on the presence of ORE1. We confirmed that ORE1 and *BFN1* are highly expressive during senescence. Our results demonstrate that senescence-induced *BFN1* expression is

regulated by ORE1. Previous studies have demonstrated the central importance of ORE1 for the control of leaf senescence and developmental PCD. Considering the possible role of *BFN1* in degradation of nucleic acids during senescence, it is assumed that ORE1 exerts its senescence promoting function partly through BFN1.

5.4. Experimental procedures

5.4.1. General

Standard molecular techniques were performed as described in **Chapter 2, section 2.4.1**.

5.4.2. Plant material

The plant material and growth conditions were as described in **Chapter 2, section 2.4.2**.

5.4.3. Plant transformation

Wild type *Arabidopsis* transformation and supertransformation of the *anac092-1* T-DNA insertion mutant with the *Prom-BFN1:GUS* was performed as described in **Chapter 2, section 2.4.4**. T0 seedlings were selected on kanamycin (50 mg/L). Kanamycin-resistant lines were analyzed by PCR for GUS reporter gene-specific amplification.

5.4.4. Constructs

Description of *BFN1-LUC* construct was given in **section 4.4.4**. Descriptions of overexpressor construct (*35S:ORE1*) and *Prom-BFN1:GUS* were given in Balazadeh *et al.* (2010a) and Farage-Barhom *et al.* (2008), respectively.

Promoter-LUC construct: The 1.0 kb *BFN1* promoter and a 0.2 kb long truncated versions (counted from the translation initiation codon) were amplified from genomic *Arabidopsis* (Col-0) DNA by PCR using an Advantage HF 2 PCR Kit (Clontech) and specific primer pairs listed for each construct (**Annex 1**). A mutated version of *BFN1* promoter (*BFN1-M-LUC*) was generated by site-directed-mutagenesis. Briefly, two short complementary promoter fragments were amplified by PCR and introduced into the final vector. Primers were used in two independent PCR reactions combining (i) forward primer (139) with reverse mutated primer (148), and (ii) forward mutated primers (147) with reverse primer (140) (**Annex 1**). The final products were isolated and purified using a QUIAGEN-PCR cleanup kit (QUIAGEN)) and used as a template for a final PCR to amplify the long version (1084 bp) of the promoter using forward (139) and reverse (140) primers (**Annex 1**). The amplified DNA fragments were cloned into the pENTR/D-topo vector (Invitrogen) to generate entry vectors. The entry vectors were then recombined into the Gateway destination vector *p2GWL7.0* (Karimi *et*

al., 2002) which is a recombination of the gateway *pBGWL7.0* (transcription reporter and *p2GW7.0* (overexpression vector) vectors (Licausi *et al.*, 2011) using the LR reaction mix II (Invitrogen) to obtain the final reporter *BFNI-M-LUC* (full-length mutated promoter) and *BFNI-S-LUC* (short promoter).

5.4.5. Histochemical and quantitative GUS assay

Histochemical GUS assay was performed as described in **Chapter 2, section 2.3.4**. Quantitative measurements of GUS activity were made by fluorometric GUS assays using 4-methylumbelliferyl glucuronide (MUG) as substrate for the GUS enzymatic reaction, in which the fluorescent product 4-methyl umbelliferone (4-MU) can be detected (Jefferson *et al.* 1987). Tissue samples were ground in GUS extraction buffer 50 mM NaH₂PO₄, 1 mM EDTA, 0.1% Triton X-100, 0.1% (w/v) sarcosine, and 10 mM dithiothreitol (DTT), and following removal of tissue debris by centrifugation at 10 000 g for 10 minutes at 4°C, the crude total protein extract was used to measure GUS activity with a Fluorescence microplate reader (FLUOstar Omega). A standard curve was prepared with 4-MU, and GUS activity was expressed as pmol 4-MU mg/ul (Jefferson *et al.*, 1987). Protein content was determined in the same sample used for the GUS assay by Bradford (Bio-Rad Protein assay) (Bradford, 1976). Tissue-specific expression was analyzed using plants of the T3 generation.

5.4.6. Dark-induced senescence

Experiments for artificial induction of senescence were performed with leaves in position 6th or 7th of the *Arabidopsis* plant rosette. The leaves were detached and incubated in the dark in containers fitted with inlet and outlet ports, and they were stored for 6-9 days in the dark at 25°C. The containers were sealed and connected to a flow-through air supply that was bubbled through sterile water to maintain humidity.

5.4.7. BFN1 protein extraction and Western Blots

Proteins for immunoblot analysis were extracted from leaf tissues. The tissue was homogenized in the presence of 150 µL extraction buffer (50 mM Tris-HCl, pH 7.5, 0.1% w/v SDS, 10% w/v polyvinylpyrrolidone, and 1 mM phenylmethylsulfonyl fluoride) in a microtube by means of a fitted pestle and a motorized drill. Following 15 minutes of centrifugation at 4°C, the soluble protein extract was assayed for protein content by Bradford assay (Bio-Rad, Hercules, CA, USA) and stored at -80°C. Protein extracts of 10-20 µg were mixed with sample buffer and boiled for five minutes before separation on a 15% SDS-polyacrylamide gel (Laemmli, 1970). Separated proteins were blotted onto nitrocellulose membranes with a gel blotter (Bio-Rad). Membranes were blocked with a solution containing 5% (v/v) nonfat milk and 0.1% Tween 20 in Tris-buffered saline for 60 minutes. The anti-BFN1 serum (Farage-Barhom *et al.*, 2008) was diluted 1:2.000 in the blocking solution and incubated with the

membrane for 12 to 16 hours at 4°C. The membrane was washed for 30 minutes in several changes of Tris-buffered saline containing 0.1% Tween 20. The secondary antibody was goat anti-rabbit IgG:horseradish peroxidase conjugate (Bio-Rad), which was diluted 1:50.000 in blocking solution and incubated with the membrane for 1 hour at room temperature. For signal detection, EZ-ECL Chemiluminescent (Biological Industries Ltd., Beit Haemek, Israel) or WesternBright ECL (Advansta Ltd, CA, USA) kits were used.

5.4.8. Dual-luciferase assay

The truncated *BFN1* promoters (*BFN1-LUC*, *BFN1-M-LUC*, and *BFN1-S-LUC*) were used as reporter plasmids. Renilla luciferase was used as an internal control and *35S:ORE1* construct was used as effector plasmid. Detailed description of the procedure is described in **Chapter 2, section 2.4.7.**

Contributions

The *ore 1-1* EMS mutant plant material was provided by Dr. Hong Gil Nam (Department of Agronomy, Korea University). Mamoona Rauf tested expression of *ORE1* and *SAG12* in *ore1-1* EMS mutant and *mir164abc* triple mutant. Dr. Amnon Lers provided seeds of the *Prom-BFN1::GUS* lines; Dr. Amnon Lers and Liliane Sorego carried out immunoblotting experiments.

Chapter 6

***VND-Interacting2 (VNI2)* is a potential down-stream target of ORE1**

6.1. Introduction

The *Arabidopsis thaliana* NAC transcription factor *VND-Interacting2 (VNI2)* has been recently identified as a key regulator of xylem vessel differentiation acting as a repressor of gene expression (Yamaguchi *et al.*, 2010). Furthermore, VNI2 also works as a mediator of signaling crosstalk between salt stress-response and leaf aging in an ABA-dependent manner (Yang *et al.*, 2011). VNI2 has a complex structure. As a NAC transcription factor (TF), it has a characteristic DNA-binding domain (DBD) at the N-terminal region. Within the DBD a potential repression-related sequence has been identified. The C-terminal region includes a putative PEST proteolysis target motif and a transcriptional activation domain (TAD) (Yang *et al.*, 2011). We have provided evidence that *VNI2* might be a direct target of ORE1 (**Chapter 4, section 4.2.1**). In fact, overexpression of ORE1 transactivates the *VNI2* promoter in *Arabidopsis* mesophyll cell protoplasts (**Chapter 4, section 4.2.3**) and ORE1 binds directly to the *VNI2* promoter *in vitro* (**Chapter 4, section 4.2.4**). Here we aimed to elucidate the signal transduction cascade that links ORE1 and *VNI2* during leaf senescence in *Arabidopsis*.

6.2. Results

6.2.1. *VNI2* Encodes a NAC TF regulated by ORE1

In **Chapter 4** we described experiments carried out to identify genes up- or down regulated by ORE1. According to our data *VNI2* is one direct target down-stream of ORE1 (tested *in vivo* and *in vitro*) (see **Chapter 4, section 4.2.1**). *VNI2* was highly up-regulated after five hours of estradiol induction in estradiol-inducible *ORE1* overexpressing lines and after six hours of constitutive overexpression in protoplasts (**Fig. 19.A**). Considering that VNI2 is another NAC transcription factor down-stream of ORE1, it motivated our interest to analyse *VNI2* expression in plants with altered levels of ORE1. We measured the expression of *VNI2* in constitute overexpressing

plants (*35S:ORE1*) and in plants loss-of-function mutants (*anac092-1* T-DNA insertion mutant); as controls we used plants transformed with the pGreen0229 empty vector (E.V.) (Skirycz *et al.*, 2006). As expected, *VNI2* was significantly up-regulated in plants overexpressing ORE1 and showed a decreased expression in the *anac092-1* mutant (**Fig. 19.B**).

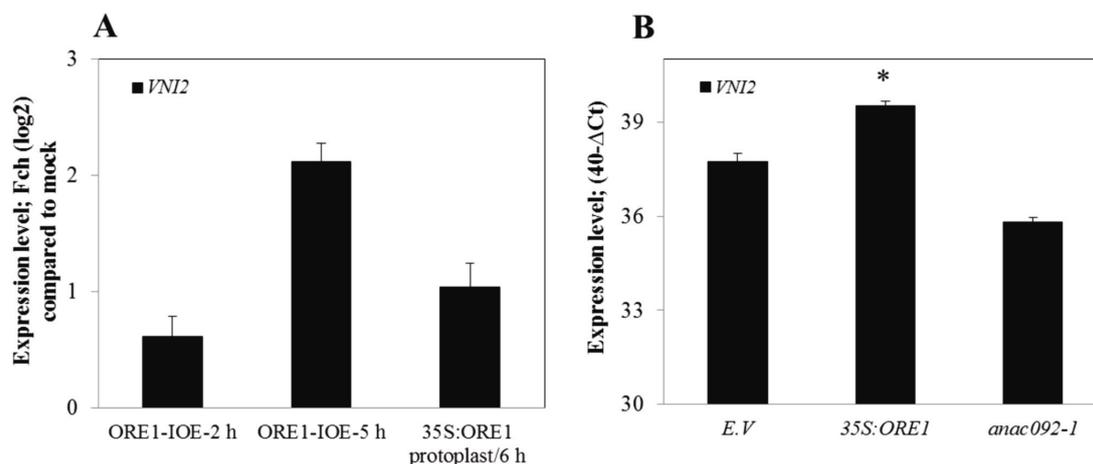

Figure 19. *VNI2* expression in *ORE1* gain- and loss-of-function mutant plants. (A) *VNI2* expression determined by microarrays (Affymetrix ATH1 array, Probe Id 245987_at) using plants and protoplasts overexpressing ORE1. (B) *VNI2* expression determined by qRT-PCR. Levels measured in estradiol-inducible overexpressing lines (*ORE-IOE*), *anac092-1* T-DNA insertion mutant and empty vector (E.V.) control plants. Statistical significance was assessed using Student's *t*-test implemented in the SigmaPlot Software. **P*<0.05.

6.2.2. *VNI2* expression in planta associates with senescence

To investigate the tissue-specific expression of *VNI2* and whether it correlates with the expression of *ORE1* (**Chapter 2, section 2.2.1**) we created *VNI2* promoter fusion lines using the *Staphylococcus* β -glucuronidase (*GUS*) as a reporter gene. We generated two promoter versions, a long version (*VNI2*_{LVProm}:*GUS*) spanning ~1.5 kb up-stream (LV) of the translation start site (SST), and a short version (*VNI2*_{SVProm}:*GUS*) comprising ~0.5 kb (SV) up-stream of the SST. The most representative expression patterns are shown in **Figure 20**. *GUS* expression driven by the *VNI2* promoters (*VNI2*_{LVProm}:*GUS* and *VNI2*_{SVProm}:*GUS*) was tested in eight independent transgenic lines per construct (T2 and T3 generations). *GUS* activity was mainly but not exclusively associated with senescent tissues throughout the plant (**Fig. 20**). Our observations confirmed published data (Yang *et al.*, 2011) and expression patterns reported in GENEVESTIGATOR (Hruz *et al.*, 2008). In the early stages of development (15-day-old seedlings), strong *GUS* activity was detected in cotyledons, margins and tips of leaves as well as roots (**Fig. 20.f**). Bolts (stems with inflorescences) exhibited faint *GUS* activity in flower buds particularly in flowers of stage 12 of development before the bud opens (**Fig. 20.c**) and in 1.0 cm primary bolts in the axis of the secondary inflorescence stem as indicated by arrows (**Fig. 20.d**). A strong and characteristic pattern was found among the axillary inflorescence axes and pedicels (**Fig. 20.e**). A closer look into opened mature flowers of stage 15 where the stigma

extends above the anthers (Smyth *et al.*, 1990) revealed strong GUS activity in the upper part of the stigma, in anthers and filaments as well as in the abscission zone (AZ), in older petals and sepals (**Fig. 20.a**). Mature opened flowers of stage 14 when long anthers extend above the stigma (Smyth *et al.*, 1990) exhibited strong *VNI2* promoter-driven GUS activity specifically in the upper part of the stigma, anthers, filaments and among the vascular tissues of sepals. Abscission zones lack GUS expression at this developmental stage (indicated by arrow) (**Fig. 20.b**). *VNI2* expression in senescent siliques was detected in the upper and bottom part of the valves near the abscission zone (AZ) (**Fig. 20.e**). These observations are in good agreement with the reported *VNI2* expression patterns derived from transcriptome analyses of senescing siliques, leaves and petals (Wagstaff *et al.*, 2009). Like other senescence-associated genes (SAGs) (e.g., *ORE1* (Balazadeh *et al.*, 2010), *ORS1* (Balazadeh *et al.*, 2011) and *BFNI* (Farage-Barhom *et al.*, 2008)), *VNI2* shares a common expression pattern in the tips and margins of senescence leaves which corresponds to the older regions of the leaves (**Fig. 20.g**). We could not identify substantial differences between the expression patterns determined by the long or short versions of the *VNI2* promoter at any of the developmental stages tested (comparison of both constructs not shown). This suggests that the region ~500 bp up-stream of the initiation codon is sufficient to drive *VNI2* promoter tissue-specific expression and that cis-regulatory elements (CREs) that confer the specific pattern observed during senescence may be within this region.

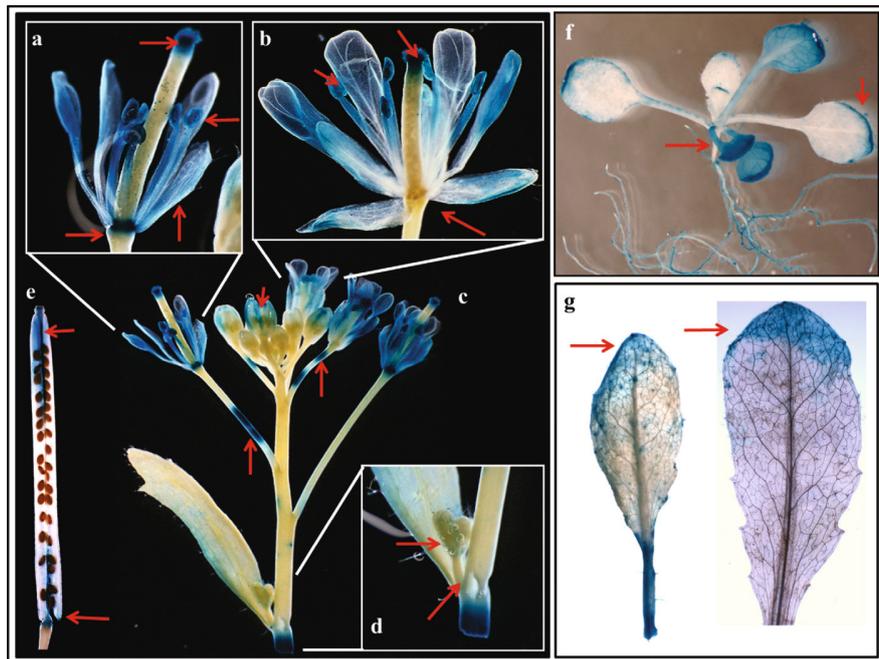

Figure 20. Tissue-specific expression of *VNI2* in *Arabidopsis*. (a-d) *VNI2* promoter-driven GUS expression in bolts of mature plants (25 days after sowing, DAS). Close-ups of (a) opened mature flower in stage 15 of development in which the stigma extends above long anthers (Smyth *et al.*, 1990). (b) Mature opened flower in stage 14 of development in which long anthers extend above the stigma (Smyth *et al.*, 1990). (c) Strong and characteristic pattern among the axillary inflorescence and pedicels (indicated by arrows). (d) One-cm bolt of primary inflorescence. (e) Mature silique (three weeks after sowing). (f) *VNI2* promoter activity in 15-day-old seedlings. (g) Enhanced *VNI2* promoter activity in the tip and margin regions of leaves from a rosette three weeks after sowing on soil (percentage of yellowing in leaves ~20%). All pictures correspond to *VNI2*_{LVProm}:GUS lines.

6.2.3. *VNI2* expression is strongly regulated by salt

A considerable number of SAGs are regulated by abiotic-stresses. In our published data we determined that *VNI2* is regulated by salt, like *ORE1*. Wild type plants were grown in a hydroponic culture system and subjected them to salt stress at two developmental stages. Stage 1: 28-day-old plants and (ii) Stage 2: 34-day-old plants. Plants were subjected to short- (six hours) or long-term (4, 9 and 12 days) salt stress (150 mM NaCl). Similarly to *ORE1*, *VNI2* expression was highly up-regulated by long-term stress. In young plants that still have expanding leaves (Stage 1), *VNI2* transcript level increased around 4-fold after four days of salt stress compared to non-treated plants (**Fig. 21**). In mature plants which were still in the vegetative stage (Stage 2, 34 days old), *VNI2* levels were up-regulated ~4-fold and ~2-fold, respectively, after nine and 12 days of salt stress (**Fig. 21**).

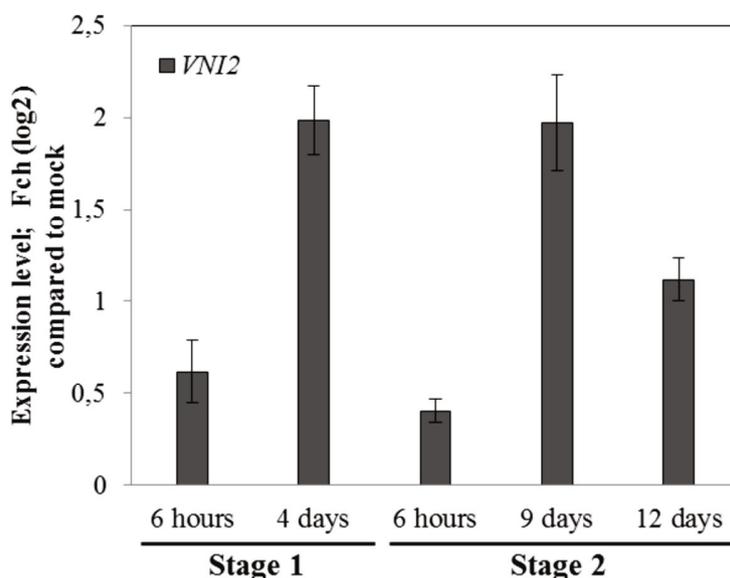

Figure 21. *VNI2* levels in response to salt stress. Expression of *VNI2* determined by quantitative real-time PCR (qRT-PCR) in plants subjected to salt stress at two plant developmental stages. Values expressed as expression ratios (salt-treated compared to control). Data are means of two independent experiments \pm Standard deviation (SD) according to published data (Balazadeh *et al.*, 2010).

6.2.4. Identification of *vni2-2* a T-DNA insertion mutant

To investigate the role of *VNI2* in leaf aging and longevity we obtained a *VNI2* T-DNA insertion line (GABI-KAT 799-H09) in the Col-0 background from the GABI-Kat consortium (Li *et al.* 2003). Homozygous *VNI2* knockout mutants (*vni2-2*) were isolated (**section 6.4.5**). The T-DNA insertion was confirmed via PCR using primers annealing between the start and stop codon of the *VNI2* open reading frame. A second combination of primers consisting of the previous forward primer and the T-DNA left border primer (LB) was used to confirm the T-DNA insertion (**Fig. 22.B**). Two homozygous plants (P1, P2) were selected based

on selection in sulfadiazine (section 6.4.6) and on-gel results using wild type as a positive control (Fig. 22.C). The band amplified from the line P1 using forward and LB primer was used to determine the exact position of the T-DNA insertion by sequencing (<http://www.eurofinsdna.com/>). In Figure 22.A a schematic representation of the protein is shown. The sequence allowed us to locate the T-DNA insertion to the third exon. It is placed within the PEST proteolysis target motif (TTDLNLLPSSPSSD; PEST score of +4.94; threshold +5.0) (Gasteiger *et al.*, 2003). This motif covers the region between nucleotides 640 - 681 that corresponds to amino acids 214-227 in the protein (Fig. 23). The T-DNA insertion lies in the middle of the PEST motif. The second half of the motif is enriched in proline and serine residues and is required to maximize the proteolytic activity of the PEST motif (Fig. 23). We could not detect a full version of the *VNI2* transcript in the homozygous *vni2-2* mutant (Fig. 22.D).

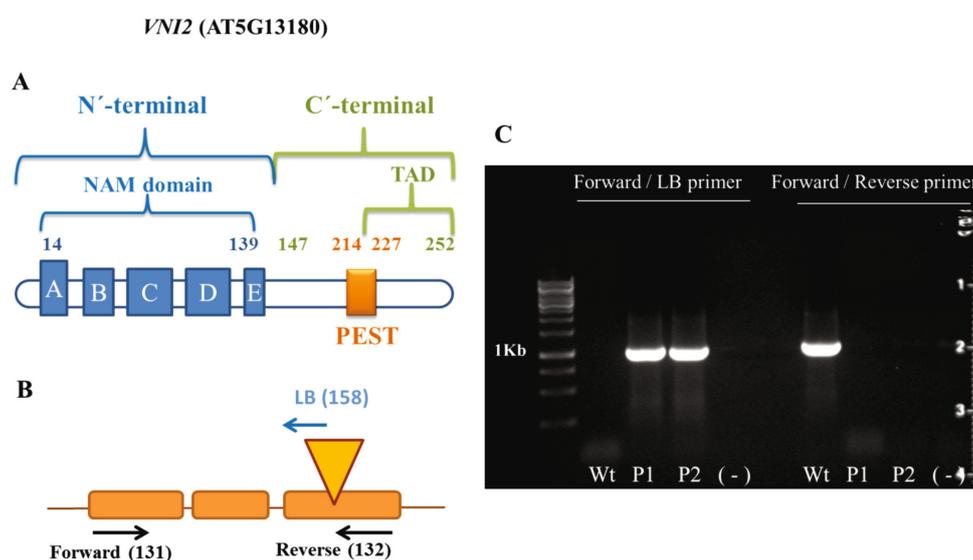

Figure 22. *vni2-2* T-DNA insertion line. (A) Schematic representation of the VNI2 protein. The N-terminal domain covers the conserved NAM domain, which contains five subdomains (A-E). The C-terminal region contains a predicted PEST domain and the transactivation domain (TAD) (protein length 252 amino acids, aa) (B) Schematic representation of the primers used to identify homozygous mutant lines. The yellow triangle indicates the T-DNA insertion point (*vni2-2*). (C) Identification of homozygous lines by PCR. Genomic DNA was used for amplification. Two homozygous plants were selected (P1 and P2). The *VNI2* transcript was amplified only in the wild type, while the *vni2-2* mutant was positive for amplification using of T-DNA left border primer.

Considering the location of the T-DNA insertion in the third exon (Fig. 23), we designed specific primers that cover the three exons (I -III) of the *VNI2* gene in gene to test transcript abundance of each exon in *vni2-2*. RNA isolated from leaves of 30 DAS plants was used to determined transcript abundance by qRT-PCR. The combination of primers used to analyze the transcript level of the third exon covered the whole PEST motif. No product was amplified using this combination of primers, while products corresponding to the first and second exon were amplified. These data suggest that *vni2-2* might be able to produce a

truncated *VNI2* transcript that may potentially lead to the generating of a truncated protein (**Fig. 23**). Further analyses are required to clarify whether this mRNA indeed produces a (partially functional) protein.

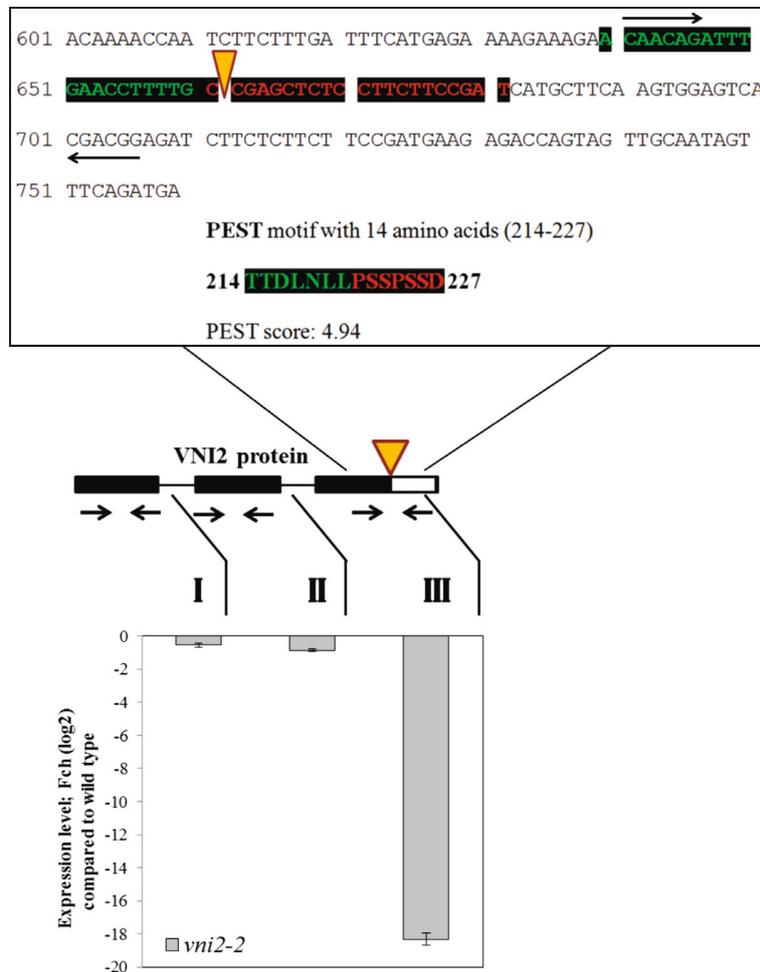

Figure 23. Amplification of *VNI2* exons by qRT-PCR in *vni2-2*. **Upper part:** The combination of primers used to analyze the transcript level of the third exon (indicated by arrows), covered the whole PEST motif region (PEST motif is indicated by colored letters). The T-DNA insertion is marked with a triangle. Red letters indicate the half of the PEST motif that confers a higher proteolytic activity of the PEST region. **Bottom part:** *VNI2* transcript abundance was analyzed using primers annealing to each exon (I - III) of the gene.

6.2.5. Bolting and leaf aging are delayed in *vni2-2*

Phenotypic analysis of *vni2-2* showed a delay in bolting in comparison to wild type (**Fig. 24.A**). We counted the number of bolted plants (80 different plants) 32 DAS as well as the number of cauline and rosette leaves at the time of flowering. Mutant plants flowered later than wild type plants under long photoperiod (16 hours light / 8 hours dark) (**Fig. 24.B**). At 26 DAS only around 20% *vni2-2* plants have bolted compared to 80% in the wild type plants.

The number of leaves at bolting was significantly less in *vni2-2* (around 10 leaves) than in wild type plants (around 18) (Fig. 24.B-C). Nevertheless, at the end of our observations (at 32 DAS) the difference in the numbers of leaves between wild type and *vni2-2* mutants was not statistically significant. Besides a delayed bolting in *vni2-2*, we observed two remarkable other features (i) a prolonged life-span with green rosette leaves even at advanced flowering stages and (ii) an increased biomass represented by bigger leaves (25. A-B).

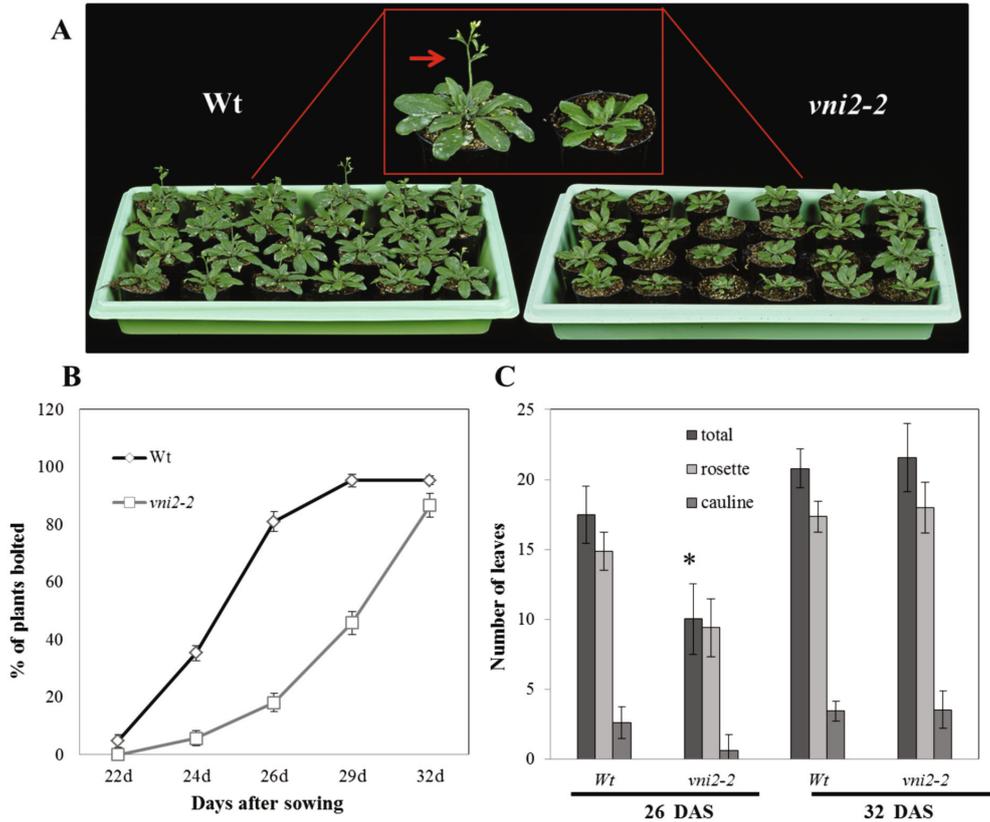

Figure 24. Delayed bolting in *vni2-2*. (A) Onset of bolting in wild type and *vni2-2* plants of the same age (26 DAS). *vni2-2* showed delayed bolting compared to wild type (bolting indicated by an arrow). (B) Percentage of bolted plants 22 to 32 DAS (C) Total number of leaves (cauline and rosette leaves) were counted at 26 DAS (beginning of counting) and 32-DAS (last day of counting). * $P < 0.05$.

To confirm our observations regarding a prolonged life span in *vni2-2* we examined the expression of four senescence associated genes (SAGs) (Buchanan-Wollaston *et al.* 2005; Balazadeh *et al.*, 2008b; Breeze *et al.*, 2011). We extracted total RNA from three independent biological replicates 29 DAS, synthesized cDNA and tested the expression of *SAG12* (At5g45890), *ORE1* (At5g39610), *BFN1* (At1g11190) and *RNS3* (At1g26820) by qRT-PCR (Fig. 25.C). The expression of three out of four SAGs (*SAG12*, *ORE1* and *BFN1*) was significantly reduced in *vni2-2* compared to wild type. This result is in accordance with the delay senescence observed in *vni2-2*.

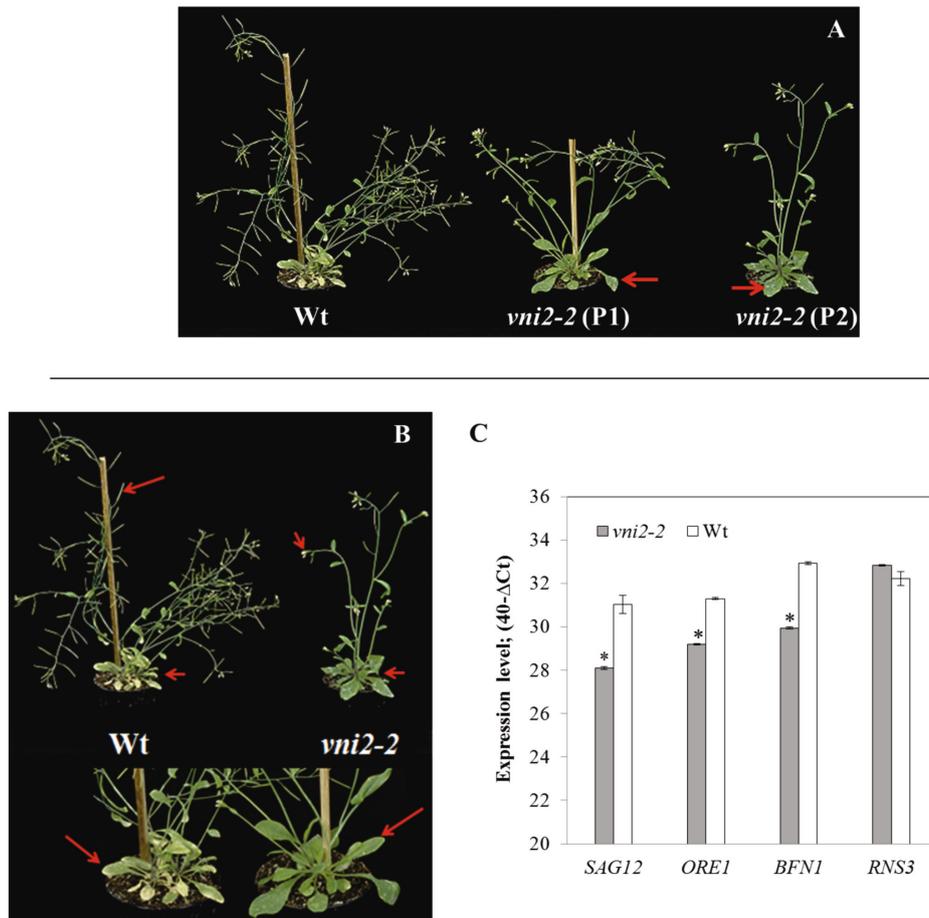

Figure 25. Prolonged life span in the *vni2-2* mutant. Upper panel: (A) Developmental delay in *vni2-2* (two different plants) compared to wild type plants at the same time after sowing. Bottom panel: Close up shows extended longevity of *vni2-2* and increased biomass represented as bigger leaves (plant age: 32 DAS). (B) Transcriptional level of *SAGs* in *vni2-2* (29 DAS) compared to wild type. *SAG12*, *ORE1*, *BFN1* transcript abundance was significantly reduced in *vni2-2*. $SD \pm 3$. (* $P < 0.05$).

6.2.6. Salt stress tolerance is enhanced in *vni2-2*

It is known that seed germination can be delayed under unfavorable environmental conditions such as high salinity (Kim and Park, 2008). Salt stress also retards plant growth and accelerates senescence (Lee and Zhu, 2010). Considering that *ORE1* and *VNI2* expression is enhanced under long-term salt stress and that *VNI2* is regulated by *ORE1*, we tested whether the response of *vni2-2* to salt stress is impaired. We assayed seed germination rate under high salinity conditions. *vni2-2* and wild type plants were grown on sterile plates with or without sodium chloride (100 mM, 150 mM and 200 mM NaCl). Germination rate was scored 15 days after sowing. Seeds were considered germinated if the radicles had penetrated the seed coats (Lee and Zhu, 2010). The assay was performed in three independent biological replicates for each salt concentration including controls. As can be seen in **Figure 26.B**, around 80% of the seeds germinated in the

absence of salt stress (Mock). As expected, the germination rate decreased concomitantly with increasing salt concentration in the medium. Nevertheless, *vni2-2* germinated better in saline conditions than the wild type (**Fig. 26.A**). There was no difference in germination rate among wild type and mutants in control conditions. At 100 mM NaCl this difference was around 2-fold. At 150 mM NaCl the difference increased to 5-fold, and at 200 mM NaCl *vni2-2* was around 7-fold more tolerant to salt stress than the wild type (**Fig. 26.B**). The negative effect of salt was already evident at the lowest concentration (100 mM). Roughly all germinated seeds in both lines developed with a notable decrease in size and exhibited yellowish color. At 150 and 200 mM NaCl only the radicles of *vni2-2* could penetrate the seed coat and generated very small leaves (**Fig. 26.A**). In contrast, nearly all wild type seeds died at 200 mM NaCl and the small percentage of seeds that germinated did not survive.

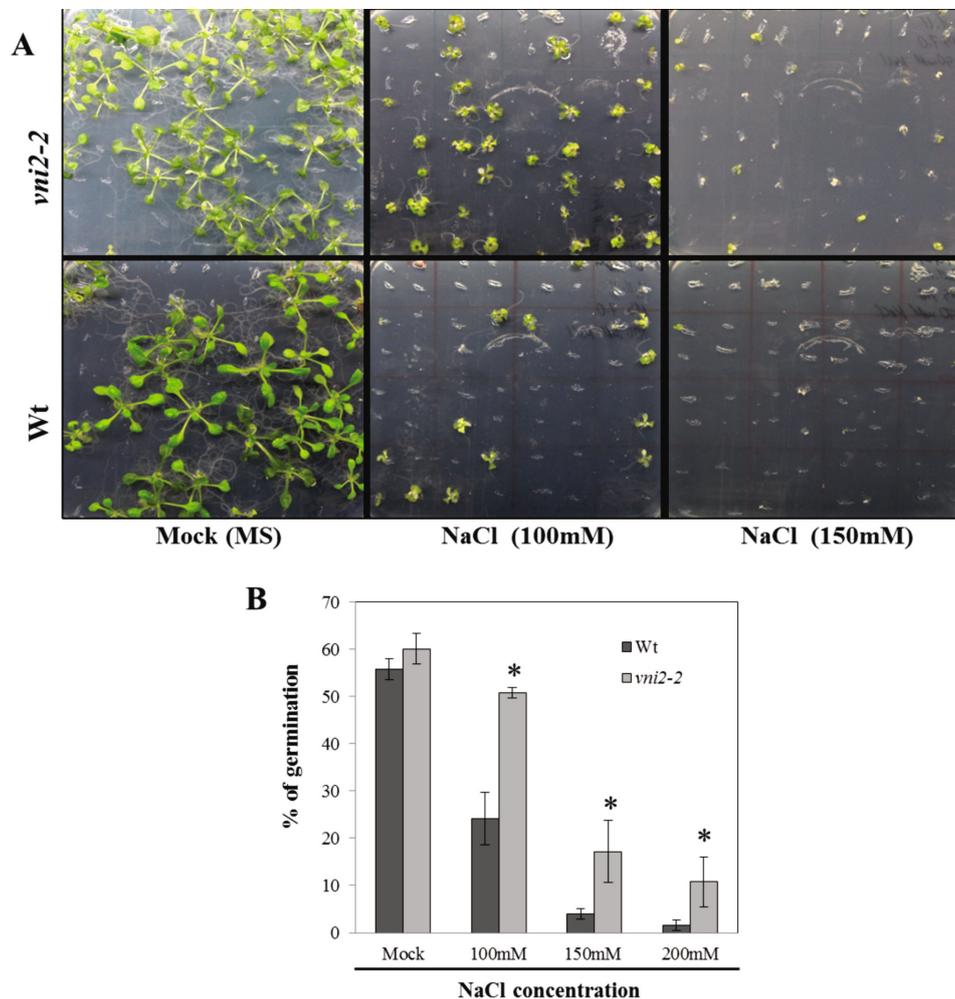

Figure 26. Salt stress tolerance is enhanced in *vni2-2*. (A) 15-DAS seedling growth under two different concentration of salt (100 and 150 mM NaCl). The *vni2-2* mutant showed enhanced salt-stress tolerance compared to wild type. (B) Germination rate of *vni2-2* mutants and wild type plants at three different salt concentrations. SD \pm 2 biological replicas and two technical replicas. * P <0.05.

6.2.7. The activation domain of *VNI2* exerts a marked influence on development and senescence regulation

Recently, Yamaguchi *et al.* (2010) established that the protein stability of *VNI2* is regulated by the PEST motif located at the C-terminal. A truncated version which lacks the PEST motif was more stable, and the full version was more stable if proteasome inhibitors were applied. Transgenic seedlings expressing the truncated version under the control of the endogenous *VNI2* promoter showed impaired xylem vessel differentiation. Moreover, constitutive overexpression of *VNI2* resulted in the formation of discontinuous vessels and slow plant growth. To examine if the role of *VNI2* in senescence requires the PEST motif and the activation domain, we generated two inducible overexpression lines using a chimeric transcription activator system (XVE) (Zuo *et al.*, 2000). We designed two versions of *VNI2* (Fig. 27.A). One version, designated *VNI2-IOE*, refers to the full protein (252 aa). The other version, *VNI2-IOE-ΔC* refers to a truncated protein lacking the C-terminal region corresponding to half of the PEST motif (221 aa) and the whole transcriptional activator. For both constructs we generated transgenic lines in the *Arabidopsis* wild type (Col-0) background. Transformed plants were selected on hygromycin and subsequently transferred to soil. Induction of *VNI2* was tested in the T1 generation; detached leaves were subjected to estradiol induction for five hours. Based on the induction level, two independent lines for each construct were selected for further experiments.

Transcript levels were determined by qRT-PCR using cDNA from seedlings of both constructs lines grown in media supplemented with estradiol (EST). Wild type seedlings in media with/without EST were used as controls. Two combinations of primers annealing to the first two exons (I, II) were used for expression analyses. *VNI2* expression was significantly higher in transgenic seedlings overexpressing the truncated version of the protein (*VNI2-IOE-ΔC*) than in plants overexpressing the full-length version (*VNI2-IOE*) compared to wild type (Fig. 27. B).

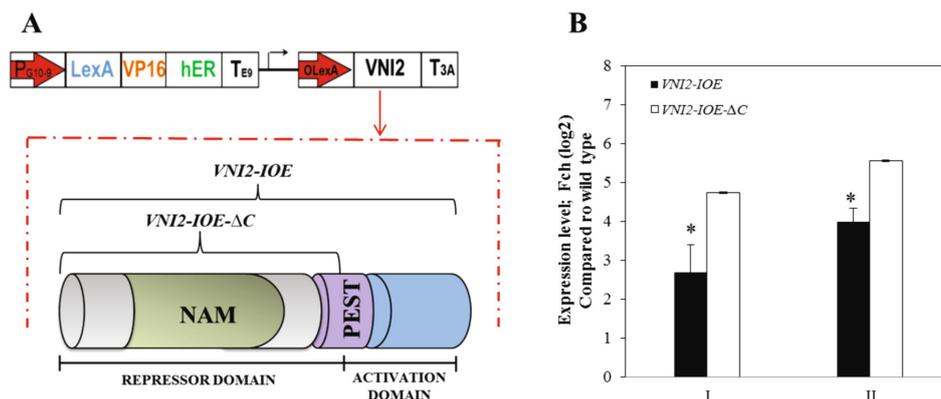

Figure 27. Differences in *VNI2* transcript level with/without the activation domain. (A) Upper: Schematic representation of the *VNI2* coding sequence used to produce estradiol-inducible *VNI2* expression lines (Zuo *et al.*, 2000a). **Bottom:** Schematic representation of the constructs used. The *VNI2-IOE-ΔC* construct lacks the whole transcriptional activation domain and almost half the PEST motif. **(B)** Transcript abundance of *VNI2* in seedlings (15 DAS) carrying the complete and the truncated version of *VNI2*. I and II correspond to primers annealing to the first and second exon of *VNI2*. SD±2 biological replicates and three technical replicates.

We detected phenotypic differences between seedlings expressing either the full or the truncated version of the protein even without estradiol induction. These differences were determined also at transcript level. Seedlings expressing the truncated version of the protein were smaller than wild type and *VNI2-IOE*, and exhibited signs of yellowing (**Fig. 28.B**). The effect was more pronounced in media supplemented with estradiol. The *VNI2-IOE-ΔC* seedlings were markedly smaller and showed increased premature yellowing, indicating an accelerated senescence. To test if these plants showed indeed accelerated senescence the expression of the senescence associated gene (SAG) *SAG12* was tested. We extracted total RNA from 15-day-old seedlings and synthesized cDNA from two independent biological replicates. It was previously shown that *SAG12* expression is exclusively detected during senescence (V., 2003). Therefore, we used its expression as a molecular marker of senescence. *SAG12* expression was significantly increased in plants over-expressing both versions of VNI2 (*VNI2-IOE* and *VNI2-IOE-ΔC*) compared to wild type. *SAG12* was markedly up-regulated in *VNI2-IOE* seedlings expressing the full version of the protein (~6-fold) and only ~3-fold up-regulated in *VNI2-IOE-ΔC* seedlings that showed more extensive yellowing. These results suggest (i) the presence of the VNI2 full-length protein positively regulates senescence and (ii) overexpression of a truncated version lacking the transcriptional activation domain and the PEST motif results in plants with considerable developmental disruptions unrelated to senescence albeit the seedlings show precocious yellowing (**Fig. 28.B**).

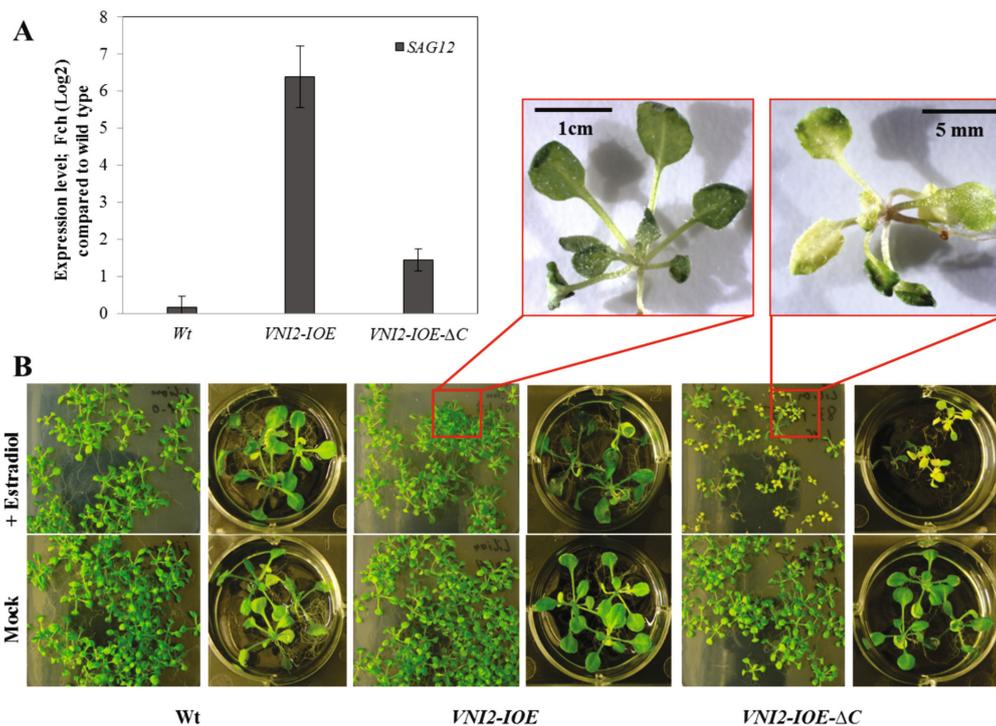

Figure 28. *VNI2-IOE* and *VNI2-IOE-ΔC* plants under estradiol induction. (A) Enhanced expression of *SAG12* in *VNI2-IOE* and *VNI2-IOE-ΔC* plants grown under estradiol induction. (B) Phenotypic analysis of *VNI2-IOE* and *VNI2-IOE-ΔC* seedlings (15 days old). Close-ups of *VNI2-IOE* and *VNI2-IOE-ΔC* plants show that plants overexpressing a truncated version of VNI2 were considerably smaller than plants overexpressing the full version of the protein.

6.2.8. *ATAF1* positively regulates *VNI2* expression

We determined that *ORE1* is positively and significantly up-regulated by *ATAF1*. We probed that *ORE1* promoter is transactivated by *ATAF1* in protoplast, suggesting that *ATAF1* is a direct regulator of *ORE1* (Chapter 2). We determined that overexpression of a CDPK named CKOR (for calcium-dependent kinase regulating *ORE1*) *in vivo* leads to an increase in transcriptional activity of *VNI2* (Chapter 3). Additionally, based on our observations that *ORE1* binds *in vitro* to a *VNI2* promoter fragment containing an *ORE1*-BS and transactivated *in vivo* *VNI2* promoter (Chapter 4) we propose that *VNI2* is a putative direct target gene of *ORE1*. In order to unravel the transcriptional network and possible regulatory loops among these NAC TFs involved in senescence and salt-stress responses we performed a series of assays. Using whole genome transcriptomics assays we uncover that along *ORE1* *VNI2* expression is significantly up-regulated by *ATAF1*. Expression profiles are based in lines overexpressing *ATAF1* under the control of an estradiol-inducible promoter (Fig. 29).

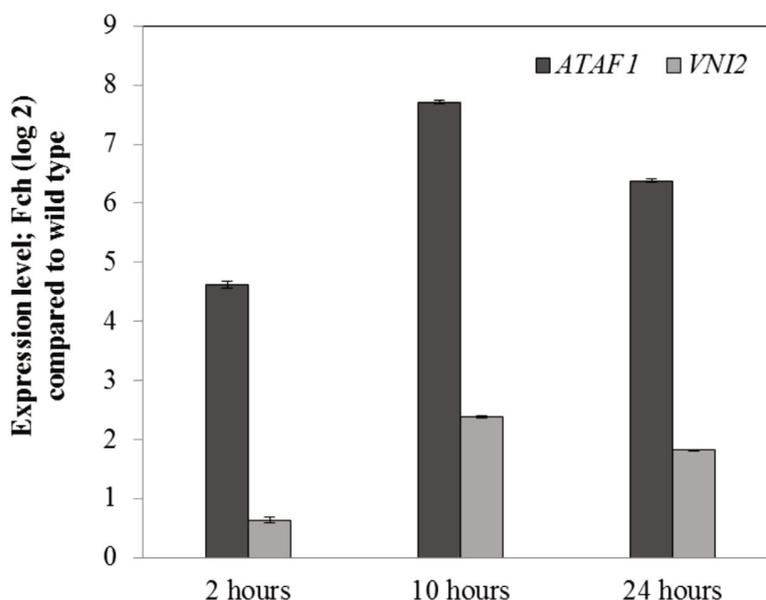

Figure 29. *VNI2* and *ATAF1* expression in *ATAF1* inducible overexpressing lines (*ATAF1*-IOE) upon estradiol (EST) induction. *VNI2* expression determined by microarrays (Affymetrix ATH array, probe Id 245987_at). Significant up-regulation (two cut-off) after 10 hours upon *ATAF1* induction. Maximal level of *VNI2* was reached after 10 hours EST induction.

The rapid induction of *VNI2* upon inducible over-expression of *ATAF1* after two hours EST induction suggests a positive control of *ATAF1* over *VNI2*. Interestingly, the expression pattern of *VNI2* highly resembles the expression pattern of *ORE1* under the same conditions (Chapter 2, section 2.2.5). Two hours after EST induction *VNI2* expression is less than 2-fold up related. Nevertheless, ten hours after EST induction *VNI2* expression is more than 4-fold up-regulated (Fig. 29). These observations suggest two hypotheses: either *VNI2* is

activated through a signal cascade in which ATAF1 activates *ORE1* and then *ORE1* directly activates *VNI2*; or ATAF1 can directly activate *VNI2* as well as *ORE1* meaning that *VNI2* activation occurs independently of *ORE1*. In order to test if *VNI2* up-regulations occurs independently or depends on *ORE1* activation by ATAF1 we used transactivation assays in mesophyll protoplasts. A *VNI2* region spanning ~1.5 kb up-stream of the translation start site was amplified by PCR from *Arabidopsis* genomic DNA (Col-0), and then cloned into pENTR/D-topo vector (Invitrogen) and recombined into the Gateway destination vector *p2GWL7.0* (Karimi *et al.*, 2002) to obtain the final reporter vector *VNI2-LUC*. The effector plasmid was the *35S:ATAF1* construct. For detail description see **Experimental procedures** in **Chapters 2 and 4**. A dual-reporter system determines the transcriptional activation of the *VNI2-LUC* promoter when ATAF1 is overexpressed. The internal control reporter, *Renilla* luciferase (*35S:RLuc*) (Licausi *et al.*, 2011) provides the parameter to normalize the measured luciferase activity. *Arabidopsis* mesophyll cell protoplasts from wild-type and *anac092-1* lines were co-transfected with the *VNI2-LUC* and *35S:ATAF1* constructs. No statistical differences in luciferase activity were detected when using either wild type or *anac092-1* mesophyll protoplasts; evidencing that *VNI2* transactivation does not requires *ORE1* and can be achieved directly by ATAF1 overexpression (**Fig. 30**).

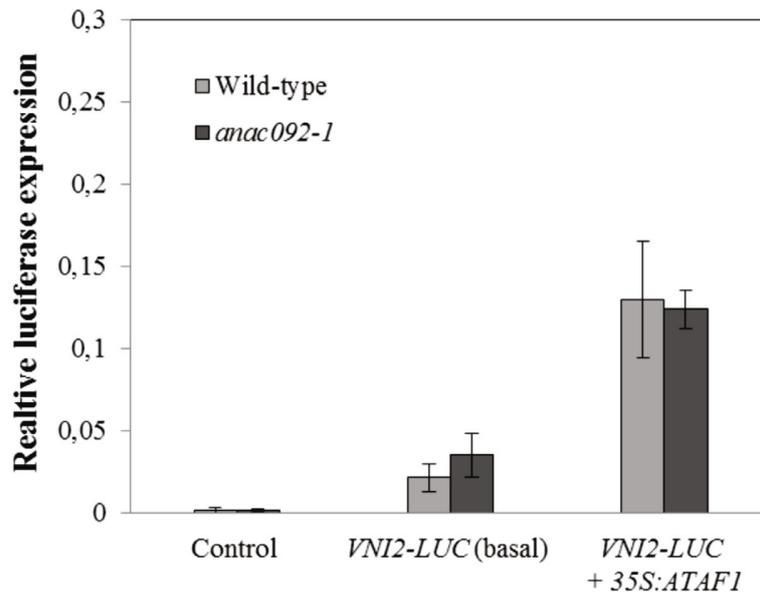

Figure 30. Protoplast transactivation assay of ATAF1 and *VNI2* promoter. *Arabidopsis* wild type or *anac092-1* T-DNA insertion mutant mesophyll protoplasts were co-transfected with *VNI2-LUC* and *35S:ATAF1*. Results are the mean of two biological replicates with three technical replicates per probe. Data were normalized to the corresponding *Renilla* luciferase activity.

6.3. Conclusions

Transcriptome analyses revealed *VNI2* as a highly up-regulated gene downstream of the key senescence regulator *ORE1* (a NAC TF). *VNI2* was preferentially expressed in senescence

tissues at different developmental stages. The CREs required for senescence-dependent expression are located within ~500 bp up-stream of the transcription start site. We confirmed that *ORE1* is a transcriptional activator of *VNI2*. Moreover, ORE1 binding to the *VNI2*-promoter was confirmed *in vitro* and *in vivo* (**Chapter 4, section 4.2.3 and 4.2.4**). Our data support the conclusion that *VNI2* is a direct target of *ORE1*.

We show that salt stress tolerance is enhanced in *vni2-2* mutants. *vni2-2* mutants also exhibited a prolonged life-span, delayed onset of bolting, higher salt stress tolerance and apparently increased in biomass demonstrating a role of VNI2 not only in the regulation of natural- and stress-induced senescence in *Arabidopsis*. The delayed senescence phenotype observed in *vni2-2* may be due to the absence of the transcriptional activation domain and the PEST motif although a truncated VNI2 protein may still be produced.

6.4. Experimental procedures

6.4.1. General

Standard molecular techniques were performed as described in **Chapter 2, section 2.4.1**.

6.4.2. Plant material

The plant material and growth conditions used were similar as described in **Chapter 2, section 2.4.2**.

6.4.3. Plant transformation

Arabidopsis transformation was performed as described in **Chapter 2, section 2.4.4**.

6.4.4. Constructs

Description of the *35S:ORE1* overexpressor line was given in Balazadeh *et al.*, (2010a). Description of the *ATAF1-IOE* and *35S:ATAF1* constructs were given in **section 2.4.3**.

***VNI2-GUS* constructs:** approximately ~1.5 kb (long version) and ~0.5 kb (short version) fragments up-stream of the *VNI2* ATG were amplified from genomic *Arabidopsis* Col-0 DNA by PCR using primers forward (133) and reverse (134) for the long version, and forward (135) and reverse (134) primers for amplification of the short version (**Annex 1**). Isolated fragments were inserted first into plasmid pCR2.1-TOPO (Invitrogen), and after sequencing fused via *Bam*HI and *Nco*I sites to the GUS reporter gene into pCAMBIA1305. 1-hygromycin (CAMBIA). The final constructs were designated as *VNI2_{LVProm}:GUS* and *VNI2_{SVProm}:GUS*.

Estradiol-inducible overexpression (IOE) constructs. The complete *VNI2* coding sequence (CDS) was amplified by PCR using leaf cDNA from *Arabidopsis* plants. We used primers forward (142) and reverse (201) (**Annex 1**). To generate a version without the transcriptional activation domain, we used forward (142) and reverse (141) primers (**Annex 1**). Both fragments were inserted into pBluescript SK and then cloned via *Xho*I and *Spe*I sites into the pER8 vector (Zuo *et al.*, 2000b). The resultant plasmids were electroporated into *Agrobacterium tumefaciens* strain GV3101/pMP90, which was used to transform *Arabidopsis* ecotype Col-0. The final vectors were named *VNI2-IOE* (complete CDS) and *VNI2-IOE-ΔC* (CDS without transcriptional activation domain). The T1 generation of transgenic seedlings was selected on MS medium supplemented with (10 mg/L) spectinomycin for 15 days.

6.4.5. Histochemical GUS assay

Histochemical GUS assay was performed as described in **Chapter 2, section 2.4.5**.

6.4.6. Identification of homozygous T-DNA insertion line

The *vni2-2* homozygous mutant was isolated from a T-DNA line (GABI-KAT 799-H09) (Li *et al.*, 2003). Firstly, lines were selected based on resistance to sulfadiazine (7.5 mg/mL). Seeds were sown on MS medium (Murashige and Skoog, 1962) supplemented with sulfadiazine (7.5 mg/mL) for 15 days. Surviving green seedlings were transferred to soil and two weeks later genomic DNA was extracted. Homozygous line was identified via PCR screening on genomic DNA using gene-specific primers forward (131) and reverse (132) together with T-DNA-specific primer LB (158) (**Annex 1**). Additionally, we determined the transcript abundance of *VNI2* by qRT-PCR using specific sets of primers covering the first exon (149-150), second exon (70-71) or the third exon (160-161) (**Annex 1**).

6.4.7. cDNA synthesis and quantitative real-time PCR (qRT-PCR)

Total RNA extraction, cDNA synthesis and qRT-PCR were done similarly as described (Balazadeh *et al.*, 2008; Caldana *et al.*, 2007). Primer sequences used for qRT-PCR analysis to quantify transcript levels of *SAG12* (At5g45890), *ORE1* (At5g39610), *BFN1* (At1g11190) and *RNS3* (At1g26820) are given in **Annex 1**. The PCR reactions were run on an ABI PRISM 7900HT sequence detection system (Applied Biosystems Appliedera, <http://www.appliedbiosystems.com/>). At least triplicate measurements were carried out to determine the mRNA abundance of each gene in each sample. The absence of genomic DNA was verified by PCR using primers forward (202) and reverse (203) designed to amplify an intergenic region of a control gene (At5g65080). cDNA was produced from 2 μg total RNA using SuperScriptT III Reverse Transcriptase (Invitrogen). cDNA synthesis efficiency was controlled by qRT-PCR amplification of transcripts from a housekeeping gene *ACTIN2* (At3g18780) using specific forward (204) and reverse (205) primers (**Annex 1**). Data analysis was performed using SDS

2.2.1 software (Applied Biosystems Applera). Amplification curves were analyzed with a normalized reporter (R_n : the ratio of the fluorescence emission intensity of SYBR Green to the fluorescence signal of the passive reference dye) threshold of 0.2 to obtain the C_T values (threshold cycle). Data were normalized to the *ACTIN2* transcript as follows $\Delta C_T = C_T(\text{gene}) - C_T(\text{ACTIN})$. The expression was measured with three replicates in each PCR run, and the average C_T was used for relative expression analyses. Relative transcript abundance was determined using the comparative $\Delta\Delta C_T$ method ($\Delta\Delta C_T = \Delta C_T(\text{condition of interest}) - \Delta C_T(\text{control condition})$) and the Fold Change (Fch) was calculated using the expression $2^{-\Delta\Delta C_T}$, where the obtained results were transformed to Log2 scale. In some cases the expression was expressed as $40^{-\Delta\Delta C_T}$ to improve the visualization of results.

Contributions

The *ORE1-IOE*, *35S:ORE1* lines and *anac092-1* T-DNA insertion mutant screening were performed by Dr. Hamad Siddiqui (Molecular Biology, Potsdam University). *ATAF1-IOE* constructs was provided by Dr. Dagmar Kupper (Molecular Biology, Potsdam University). *35S:ATAF1* construct and ATAF1 transcriptome data were provided by Prashant Garapati, Ph.D student of Prof. Dr. Mueller-Roeber's Group.

Discussion

The recent years have seen considerable progress with respect to the dissection of the molecular pathways controlling the induction and progression of senescence in plants, mainly in the model plant *Arabidopsis thaliana*. Leaf senescence determines the end of leaf development and constitutes an efficient recycling process that involves the breakdown of cellular organelles, the hydrolysis of different macromolecules, and the mobilization of nutrients from senescent tissues to young and reproductive organs. An example of the important role that recycling processes play in plants is the increase in nitrogen-use efficiency by resorption of foliar nitrogen (N) (Himmelblau and Amasino, 2001). N is stored in younger and reproductive tissues and can be used for early growth in the subsequent progeny to supply the demands of developing foliage (Kang *et al.*, 1982). Therefore, senescence favors the fitness of plants and is thought to be an evolutionary acquired process (Nam, 1997; Noodén and Leopold, 1988). Leaf senescence must be synchronized and tightly controlled to ensure not only the disassembling of cellular components like photosynthetic apparatus in early senescence, but also the conservation of cellular compartmentalization (Hörtensteiner and Feller, 2002), as well as nucleus and mitochondria integrity, until advanced senescence stages (Noodén and Guamet, 1996; Noodén and Leopold, 1988). Transcriptome analysis of senescence leaves in *Arabidopsis thaliana* revealed a complex network of genes involved in the process, including many transcription factors (TFs) (Buchanan-Wollaston *et al.*, 2005; Gepstein *et al.*, 2003; Balazadeh *et al.*, 2008; Breeze *et al.*, 2011). TFs recognize specific regions on the promoter region of targets regulating their activation or repression. NAC (*NAM*, *ATAF*, and *CUC*) TFs represent a large fraction of the genes regulated during developmental and induced senescence in many plant species, including monocots and dicots, some of which are of particular agronomic importance (Balazadeh *et al.*, 2008; Buchanan-Wollaston *et al.*, 2005; Christiansen *et al.*, 2011; Guo *et al.*, 2004). The importance of the NAC TF ORE1 (also called *ANAC092*, *AtNAC2*, or At5g39610) is well documented as a senescence regulatory protein (Balazadeh *et al.*, 2010a; He *et al.*, 2005; Kim *et al.*, 2009; Ooka *et al.*, 2003). Its role in senescence was first described by Kim *et al.*, (2009) who observed that the *oresara1 (ore1)* EMS mutant displayed a delayed senescence phenotype. Despite the importance of ORE1 as a positive regulator of senescence, mechanisms and elements of its regulatory pathway are still poorly understood. In this study, we describe two previously unknown regulatory pathways up-stream of ORE1, and we addressed the challenging task of identifying potential direct targets of ORE1.

Up-stream regulation of *ORE1*

As we described in **Chapter 2**, *miR164* is the only regulator up-stream of *ORE1* described so far. *miR164* together with *EIN2* and *ORE1* form a trifurcate feed-forward loop. *EIN2* is a membrane-spanning protein whose biochemical function is still unknown, but genetic studies indicate that it is absolutely required for ethylene signaling (Alonso *et al.*, 1999; Kim *et al.*, 2009). It has been shown that *ORE1* expression increases in a leaf age-dependent manner, apparently through induction by *EIN2*. *miR164* targets *ORE1* mRNA and down-regulates its expression. Nevertheless, the mechanism that governs an age-dependent decrease in *miR164* expression remains unknown. All that can be speculated is that *miR164* functions in younger leaves as a “guard” against premature overexpression of *ORE1*. Kim *et al.* (2009) proposed that this feed-forward loop exists to guarantee that senescence and the accompanying programmed cell death occurs when leaves are aged (Kim *et al.*, 2009). Notably, a screening for down-stream targets of the MADS-box transcription factor *SEPALLATA3* (*SEP3*) revealed that *SEP3* binds to the *ORE1* promoter. Chromatin immunoprecipitation (ChIP), followed by next-generation sequencing (ChIP-Seq) or hybridization to whole-genome tiling arrays, revealed four aspects of particular interest: (i) *SEP3* binds to the *ORE1* promoter *in vivo*; (ii) *ORE1* is *SEP3* target-specific during stamen and carpel development; (iii) DNA-binding sites of *SEP3* are predominantly located a few hundred base pairs directly up-stream of the ATG of its targets; and finally, (iv) ChIP-Seq data revealed a dependency between the presence of perfectly matching CArG boxes and the binding of *SEP3 in vivo*.

In this study, we report for the first time two mechanisms that positively influence *ORE1* expression. First, using transcriptional profiling, we identified that *ORE1* expression is up-regulated by the NAC transcription factor *ATAF1*. Moreover, co-transfection of the *ORE1* promoter (*ORE1-LUC*) together with *35S:ATAF1* leads to transactivation of the promoter in mesophyll protoplasts, suggesting a direct interaction between *ORE1* promoter and *ATAF1* (**section 2.2.5**). Interestingly, *ATAF1* also transactivates *VND interacting factor 2* (*VNI2*), another NAC TF that we characterized in this study as a putative direct target of *ORE1*. The possible interaction between *ATAF1* and *VNI2* mediated by *ORE1* will be further described in this discussion.

The second mechanism we described in this work was discovered in collaboration with the group of Prof. Dr. Tina Romeis from the Freie Universität in Berlin. They performed a phosphoproteomic approach that revealed that *CKOR*, a calcium-dependent protein kinase (CDPK), is able to phosphorylate *ORE1*. We found that overexpression of *CKOR* in wild type mesophyll protoplasts led to a marked increase in the transcriptional activation of the *ORE1* direct target *BFN1* and the putative targets *VNI2* and *RNS3* (**Section 3.2.1**). On the contrary, the overexpression of *CKORM*, which is unable to phosphorylate its targets, led to a decreased *BFN1* promoter activation but did not affect the activation of *VNI2* and *RNS3*. It is widely acknowledged that phosphorylation and dephosphorylation of transcription factors

can directly regulate distinct aspects of their function (Whitmarsh and Davis, 2000). *ORE1*, *BFNI*, and *VNI2* are senescence associated genes (SAGs) (Balazadeh *et al.*, 2008; Breeze *et al.*, 2011; Buchanan-Wollaston *et al.*, 2005) and the S-like RNase *RNS3* gene is induced during phosphate (Pi) starvation and has been associated with the nutrient remobilization process (Bariola *et al.*, 1994; Taylor *et al.*, 1993). If we assume that phosphorylation of ORE1 by CKOR enhances its transcriptional activity, we would expect that an increase in phosphorylated ORE1 level would, in turn, result in a higher transcriptional activity. We observed that *BFNI*, whose expression is strongly up-regulated by ORE1, shows a significant increase in transcriptional activation when the amount of phosphorylated ORE1 increases (achieved by the overexpression of CKOR in mesophyll protoplasts). This tight transcriptional dependency is further supported by the significant reduction in *BFNI* activation if a mutated version of CKOR is overexpressed in mesophyll protoplasts. In the case of *VNI2* and *RNS3*, the overexpression of a mutated version of CKOR did not lead to a reduction in transcriptional activity, unlike *BFNI*. It can be assumed that both genes are strongly up-regulated by ORE1 phosphorylation. Nevertheless, it is plausible that *VNI2* and *RNS3* require a higher accumulation of ORE1 to be activated, and the ORE1 concentration in wild type protoplast, concurrently with the overexpression of a mutated version of CKOR that binds but is unable to phosphorylate ORE1, contributes to make any changes in transcriptional activity indistinguishable from the basal expression. In the Outlook section at the end of the discussion, a set of experiments is proposed to shed light on the role of ORE1 phosphorylation in regulating its activity.

ORE1, as well as most of its putative targets, have been characterized in ABA-dependent responses to stresses such as salt stress (**section 2.2.3 and 6.2.3**) (Balazadeh *et al.*, 2010b; Jiang *et al.*, 2011; Yang *et al.*, 2011). The role of phosphorylation in ABA-dependent regulation of transcriptional expression has been well documented (Furihata *et al.*, 2006; Lopez-Molina *et al.*, 2001; Zhu 2002). Thus, it may be suggested that phosphorylation of ORE1 by CKOR integrates a regulatory pathway involved in both developmental and stress-induced leaf senescence. Further analyses are required to elucidate the exact role of this novel ORE1 regulatory pathway.

Tissue-specific expression of *ORE1* gives direct insights linking *ORE1* with germination, floral development, and senescence

We have shown that tissue-specific promoter activity of *ORE1* is not restricted to senescent tissues in *Arabidopsis* or tobacco (*Nicotiana tabacum*) transformed with the same chimeric gene. In both plant species, *ORE1* promoter expression shared the same tissue-specific patterns in almost all the evaluated tissues and organs. During early developmental stages, *ORE1* promoter activity was detected in roots and was particularly enhanced in embryos from mature seeds and cotyledons of 15-day-old seedlings in both species (**section 2.2.1**). These observations are in agreement with previous studies that reported *ORE1* promoter

expression during lateral root development (He *et al.*, 2005), and in embryos under different stress conditions (Penfield *et al.*, 2006). Cotyledons are embryonic leaves that undergo a fast tissue differentiation (Fridlender *et al.*, 1996) and serve as storage to supply nutrient demand. We know that many *ORE1* up-regulated genes that are related to senescence share common patterns during the last stages of seed development (Balazadeh *et al.*, 2010a). Nevertheless, the biological relevance of this common pattern has not yet been studied. Seed germination shares some clear similarities with leaf senescence; both involve the degradation and transport of macromolecules, and the organs involved (leaves and cotyledons) keep structural similarities. Nevertheless, this does not account for the particular expression in mature embryos of *Arabidopsis* and tobacco. Interestingly, we have found a recent discovery that describes *ORE1* expression during seed germination. It has been shown that in *Arabidopsis* seeds, glutamate decarboxylase (GAD) catalyze the unidirectional decarboxylation of glutamate to form γ -aminobutyric acid (GABA) (Fait *et al.*, 2011). Fait *et al.* (2011) described that GABA is strongly associated with early seed germination. In plants, glutamate (Glu) metabolism is pivotal for efficient N incorporation, and its levels are maintained under tight regulation (Forde and Lea, 2007; Stitt and Fernie, 2003). Furthermore, accumulation of GABA is associated with enhanced amino acid contents and associates with an up-regulation of genes involved in the degradation of proteins and cellular components (Fait *et al.*, 2011). Hyperaccumulation of GABA enhanced the expression of two senescence associated genes (SAGs), i.e. *ORE1* and *SAG21* (*SENESCENCE-ASSOCIATED GENE 21*), as well as *DOG1* (*DELAY-OF-GERMINATION1*), which is one of the major regulators of seed dormancy (Bentsink *et al.*, 2010). Their results highlight a link between seed maturation and the expression of *ORE1*. However, our promoter expression analyses are based on wild type seeds carrying an *ORE1* promoter fusion (*ORE1:GUS*) that should not hyperaccumulate GABA. Moreover, according to our published germination assays, we suggested that *ORE1* might contribute to seed dormancy, which may be partly lost or enhanced, at least under salt stress, in *anac092-1* T-DNA insertion mutants and *35S:ORE1* overexpressors, respectively (Balazadeh *et al.*, 2010a). The enhanced *ORE1* promoter activity observed in embryos (imbibed in water for 12 hours before testa removal) suggests that *ORE1* is more deeply implicated in seed germination than has been considered so far. Additional studies are required to elucidate the signaling pathways governed by *ORE1* during seed germination.

The promoter expression of *ORE1*, as identified by GUS staining, is in accordance with the role of *ORE1* during senescence. The expression along the leaf blade is consistent with the reported progression of aging from the tip to the base of leaves due to remobilization of nutrients out of the leaf and in the direction of the rest of the plant organs (Hill, 1980). *ORE1* promoter activity was also detected in floral organs of mature opened flowers in the carpel/pistil, especially in the upper region of the stigma. This observation is in agreement with the recent discovery that *Arabidopsis* unfertilized/fertilized carpels exhibit senescence first in the stigma, and then it progresses from basal to apical ovules (Carbonell-Bejerano *et al.*, 2010). Furthermore, *ORE1* has been reported as up-regulated during carpel senescence

(Carbonell-Bejerano *et al.*, 2010). *ORE1* expression was strongly evident in mature anthers, whereas it was absent in immature anthers (**section 2.2.1**). Notably, GUS staining, driven by the *ORE1* promoter, was also detected in the tip region of the stigma in *Arabidopsis* unfertilized flowers (**section 2.2.1**), suggesting that *ORE1* is not exclusively involved in floral senescence, but also during early developmental stages.

Recently, two works linked *ORE1* with flower development. First, whole transcriptome analyses and chromatin immunoprecipitation assays, combined with massive parallel DNA sequencing (ChIP-Seq), were used to characterize the down-stream regulatory pathway of *SEPALLATA3* (*SEP3*). *SEP3* is a MADS-box TF that plays a crucial role in the transition from vegetative to reproductive growth and finally to floral meristems (Kaufmann *et al.*, 2009). It was found that *SEP3* binds to the *ORE1* promoter *in vivo* and that *ORE1* is a *SEP3* target specifically during stamen and carpel development. The *ORE1* promoter displays two perfect CArG boxes, one C[AAAAAAA]GG located at position -601 bp (from the ATG) and the other C[AATTATT]GG located at position -225 bp (from the ATG); a third box located within the 5'UTR differs only one nucleotide from the perfect CArG matching C[CTATTA]GG (position -5 bp). Moreover, Al-Daoud *et al.*, (2011) have found that *ORE1* promotes floral transition under short-day photoperiods. Results from other research groups, taken together with our results (**section 2.2.1**), suggest it is feasible that *ORE1* may play a role during early flower development that has not yet been explored, and it offers a new facet of *ORE1* that is complementary to its role as a master regulator of leaf senescence.

ORE1 5'UTR contains important regulatory elements required for senescence-specific expression

In an attempt to characterize the promoter region essential for the characteristic senescence associated pattern of *ORE1* expression, we performed promoter deletion analyses. Our results give insights into the pivotal role of the 5'UTR in maintaining the characteristic expression of *ORE1* during senescence. Nevertheless, a visible reduction in the strength of the signal indicates that other elements outside the 5'UTR are needed to reach the high expression levels observed during senescence (**section 2.2.4**). It has been demonstrated that in some particular cases, the region that is up-stream of the TATA box is not essential to reach high levels of expression, and that this particular feature associates with the presence of pyrimidine-rich sequences (5UTR-Py-rich stretch) in the 5'UTR. The Py-rich stretches seem to have a positive effect on the overall expression level of a gene, as seen in tomatos (Daraselia *et al.*, 1996) spinach (Bolle *et al.*, 1994), Chinese wild *Vitis pseudoreticulata* (Xu *et al.*, 2011), rice, and *Arabidopsis* (Xue *et al.*, 2008). Recently, it has been demonstrated that actin genes, from bryophytes to angiosperms, include a 5UTR-Py-rich stretch that confers high levels of transcription (Vitale *et al.*, 2003; Weise *et al.*, 2006). Interestingly, we found that the *ORE1* promoter contains two Py-rich stretch motifs in its 5'UTR. On the one hand, we have shown that plants transformed with the *Prom6-ORE1:GUS* construct that contains two predicted TATA boxes but lacks both

5UTR-Py-rich stretch motifs, lose the senescence-specific pattern from the tip to the base of the leaves (**Section 2.2.4**). On the other hand, plants overexpressing a short fragment of the 5'UTR (*Prom3-ORE1:GUS*) that contains one 5UTR-Py-rich stretch maintain the leaf senescence specific expression pattern, albeit at a much lower level. Our results suggest a pivotal role of the 5UTR-Py-rich stretch motifs. The fact that plants transformed with the *Prom3-ORE1:GUS* construct display GUS activity suggests the presence of an alternative start codon ATG since the predicted TATA boxes lie up-stream of this fragment. Interestingly, despite the high homology between *ORE1* and *ORS1* (*ORESARAI SISTER1*), an evolutionary closer NAC TF (Balazadeh *et al.*, 2011; Ooka *et al.*, 2003), *ORS1* does not contain any 5UTR-Py-rich stretch within its promoter (data not shown), confirming that *ORE1* 5'UTR conserves typical features and plays an important role in *ORE1* up-stream regulation. To conclusively probe the contribution of the 5'UTR to the *ORE1* expression pattern in senescent tissues, two approaches may be taken. The first is to replace the *ORE1* 5'UTR with a standard 5'UTR such as the GSTF8 minimal promoter (Thatcher *et al.*, 2007). We would expect a minimal promoter to completely abolish the senescence-specific pattern of expression. The second approach is to mutate both 5UTR-Py-rich motifs present in the 5'UTR, which should also lead to abolishment of the senescence-specific pattern of expression.

Defining the *ORE1* regulon based on a genome-wide analysis

The rate at which individual genes are transcribed is controlled by the binding of transcription factors (TFs) to their up-stream promoter regions. Over 2,000 TFs are encoded by *Arabidopsis* (Pérez-Rodríguez *et al.*, 2010). Nevertheless, so far only a minority (around one-third) of all TFs have been functionally characterized in *Arabidopsis*. The determination of the regulatory circuits controlled by each TF, and the identification of the cis-regulatory elements (CREs) for all genes, have been identified as two of the goals of the Multinational Coordinated *Arabidopsis thaliana* Functional Genomic Project by the Multinational *Arabidopsis* Steering Committee (June, 2002) (Davuluri *et al.*, 2003).

Recently, high-resolution temporal profiling of transcripts during *Arabidopsis* leaf senescence revealed a distinct chronology of the process and its regulation (Breeze *et al.*, 2011). Surprisingly, this model of the senescence regulatory network identified *ORE1* as a master regulatory element that controls several genes implicated in leaf senescence. Therefore, we combined three different approaches to unravel key elements in the architecture of the *ORE1* regulatory network. First, a transcriptome analysis included short- and long-term induction of *ORE1* in order to identify putative direct target genes (**section 4.2.1**). Next, we characterized the *ORE1* consensus binding site (BS) to identify *ORE1*-BSs in the promoter region of putative *ORE1* targets (**section 4.2.2**), and we selected a group of genes for further confirmation of the direct interaction with *ORE1* (**section 4.2.3 and 4.2.4**). Finally, we characterized the genes at the molecular and physiological level to be able to categorize them as direct targets. (**Chapters 5 and 6**).

Based on our previous work (Balazadeh *et al.*, 2010a), we have identified a set of differentially expressed genes after inducible over-expression of ORE1, and we confirmed some by qRT-PCR. Additional global transcriptome analyses were carried out. We incubated *ORE1-IOE* seedlings for two hours and five hours in estradiol (EST), and we constitutively overexpressed ORE1 for six hours in *Arabidopsis* mesophyll protoplasts. In total, we found 711 genes up- and 273 genes down-regulated in the three experiments. As expected, upon *ORE1* overexpression, we observed a significant over-representation of genes involved in metabolism and degradation among the up-regulated genes. The significant over-representation of genes from these functional categories may be due to the prevalent role of degradation of different macromolecules as part of the mechanism of nutrient salvage that occurs in the plant during senescence (Bleecker, 1998). Considering we found more genes up- than down-regulated, and we were able to identify 17 genes commonly up-regulated but none commonly down-regulated in all three data sets, we propose that ORE1, like most NAC TFs, functions as a transcriptional activator. Among these 17 putative targets are genes encoding proteins for degradation and dismantling processes such as lipases, kinases, synthases, hydrolases, and nucleases (Balazadeh *et al.*, 2003). We found six TFs that were up-regulated after five hours of ORE1 induction. All of them were commonly up-regulated after five hours inducible overexpression or six hours constitutive overexpression. The TFs include one zinc-ion binding factor (At2g28200), one signal transduction response regulator (At2g40670), one *MYB TF* (At3g10590), and three members of the NAC TF (*ANAC010*, *ANAC041*, *VNI2*). Thus, most of the up-regulated TFs belong to the NAC TF family, highlighting the predominant role of this family in leaf senescence (Buchanan-Wollaston *et al.*, 2005; Guo and Gan, 2004; Guo and Gan, 2012). The fact that overexpression of ORE1 leads to the up-regulation of 711 genes, most of which are SAGs, and to the up-regulation of six TFs, highlights the importance of *ORE1* as a key regulator of leaf senescence. Considering that six TFs are significantly up-regulated also underlines the apparent fact that not many transcriptional networks are activated down-stream of ORE1, and it is tempting to speculate that *ORE1* expression plays a pivotal role in the progression rather than the onset of senescence. Our results strongly support the importance of the molecular characterization of regulatory pathways governed by NAC TFs, especially ORE1, not only during senescence but also in *Arabidopsis* development.

Validation of putative direct targets of ORE1 and their functional characterization

Several members of the NAC TF family, including *ORE1/ANAC092/AtNAC2* (Guo and Gan, 2006) and *ORS1/ANAC059*, have been shown to positively regulate leaf senescence in *Arabidopsis* (Balazadeh *et al.*, 2011). Knocking out the function of each of those genes generates a delay-of-senescence phenotype. In contrast, other members of the NAC TF family, like *VNI2/ANAC083* (Yang *et al.*, 2011) and *JUB1/ANAC042* (Wu *et al.*, 2012), have recently been shown to negatively regulate leaf senescence and enhance plant longevity in *Arabidopsis*. Despite the fact that *ORE1* and *ORS1* are paralogues that exhibit evolutionary

conservation (Balazadeh *et al.*, 2011) and share a common function as positive regulators of leaf senescence, only eight genes are commonly up-regulated by both TFs upon inducible overexpression (At3g01830, At3g61190, At2g32680, At5g38710, At5g39520, At3g29250, At4g27280 and At3g61930) (Balazadeh *et al.*, 2011). All overlapping genes are SAGs, but only At5g39520 that encodes an unknown protein is among the 17 genes commonly up-regulated by *ORE1* overexpression. Thus, overexpression of a single senNAC TF (senescence-associated NAC transcription factor) affects specific down-stream genes, suggesting that functional redundancy between NAC genes controlling senescence is limited. This can be explained if each of those senNACs controls a specific or partially specific subset of down-stream target genes, which is essential for the correct timing of the onset and progression of senescence. Therefore, unraveling the gene regulatory network administrated by senNAC TFs and discovering the specificity of those regulations is of particular importance. Nevertheless, direct or indirect regulation between senNACs and their putative targets can only be determined experimentally. It is well known that characterization of the sequences bound by a transcription factor is an essential step in the identification of its true targets. The ORE1 binding site was originally reported by Olsen *et al.* (2005). However, recent studies demonstrated that sequences bound by NAC TFs are rather long and include two consensus motifs separated by a spacer of few bp (base pairs) (Balazadeh *et al.*, 2011; Xue, 2005; Wu *et al.*, 2012). The binding affinity of ORE1 to certain oligonucleotides *in vitro* was evaluated by the DNA-binding-protein-CELD method (DBP-CELD). The binding sequence of ORE1 was characterized as containing the two core motifs (RMGTR) and (YACGY) spaced apart by 5-6 bp. Thus, the ORE1 binding site (ORE1-BS) was determined to be RMGTR(5-6n) YACGY (**section 4.2.2**).

We focused our efforts to elucidate ORE1 directly from indirect interactions within a subset of six highly up-regulated genes. We selected *BFNI* (At1g11190), *RNS3* (At1g26820), *SINAI* (At3g13672), and *SAG29* (At5g13170) from the 17 commonly up-regulated genes, and we selected *ORE1* and *VNI2* based on (i) the novel hypothetical model proposed by Breeze *et al.* (2011) that predicts an autoregulatory feedback loop for *ORE1* and shows *VNI2* as a possible ORE1 direct target and (ii) the strong up-regulation of *VNI2* in our long-term transcriptome analyses (**section 4.2.1**). We tested whether ORE1 was able to transactivate the promoter regions of those six putative targets *in vivo*. Our results show that overexpression of ORE1 transactivates the expression of *BFNI*, *VNI2*, and *RNS3* (**section 4.2.3**). In the case of *ORE1*, we were unable to identify the proposed autoregulatory feedback loop. Based on our results, we decided to test the ability of ORE1 to bind *in vitro* by EMSA to ORE1 binding sites (ORE1-BSs) identified *in silico* in the promoters of *BFNI*, *VNI2*, and *RNS3*. Additionally, we included *SINAI* to test whether non-significant transactivation *in vivo* correlates with no binding *in vitro* (**section 4.2.4**). The selected genes contained more than ten different versions of ORE1-BSs taken as ORE1-BS sequences containing at least the first core motif. Nevertheless, in general, only the longest ORE1-BS found in each promoter was considered for the EMSAs. We found that ORE1 is able to bind to all tested promoters *in vitro*, but

the binding affinity was different among them. Based on the intensity of the band in the retardation gels, we were able to determine that ORE1 exhibits the highest affinity to the BS in *VNI2*. The oligonucleotides tested for *RNS3* and *SINAI* contained 5 bp and 11 bp long ORE1-BSs, respectively, and for the most part lacked the second core of the ORE1-BS. In this study, we characterized for the first time the longest consensus sequence that corresponds to the ORE1-BS and is probed by two different methods (DBP-CELD and EMSA). ORE1 binding affinity is highly dependent on the presence of both core motifs. We found that ORE1 overexpression results in a strong transactivation of *RNS3 in vivo*, and only a slight binding affinity *in vitro*. Additional EMSAs are required to pin-point the ORE1-BSs that causes the strong *RNS3* transactivation *in vivo*. Currently, we have better candidates that may fit as ORE1-BS in *RNS3*.

Based on these observations, we aimed to prove that ORE1 binds directly to these putative target genes *in vivo* by Chromatin Immunoprecipitation (ChIP) using two different tags linked to ORE1. In both cases, we used transgenic plants expressing ORE1 tagged with the green fluorescence protein (GFP) or a newly developed HaloTag (Urh *et al.*, 2008). This was the first attempt focused on the implementation of HaloTags in plants, and it represented a challenge to implementing new methods for the characterization of down-stream regulatory pathways in TFs in plants. In the case of ORE1-GFP, the cassette contains the constitutive 35S promoter, whereas ORE1-HaloTag is under the control of an estradiol-inducible promoter. Striking results were obtained in both cases. As expected, we were able to obtain high expression of ORE1, and we were able to determine the subcellular location of ORE1 in the nucleus of guard cells in *Arabidopsis* leaves (**Annex 6**). Nevertheless, none of the selected putative targets that are highly regulated by ORE1 were induced in those plants. In both cases, constructs were confirmed by sequencing for the presence of the HaloTag and GFP on transformed plants and by ORE1 expression. One possible explanation for these results is that the linked tag placed at the end of the C-terminal region of ORE1 blocked or restricted the interaction with target promoters and, therefore, expression of ORE1 putative targets was not detectable. In order to probe this hypothesis, we suggest transforming *Arabidopsis* with a different cassette in which the Tag is fused to the N-terminal region. Although we were unable to check the binding of ORE1 to the target promoters by ChIP, different assays in planta strongly support the hypothesis that *BFN1*, *VNI2*, and *RNS3* are direct targets of ORE1.

We selected *BFN1*, *RNS3*, *SINAI*, *SAG29*, and *VNI2* to test if they are direct targets of ORE1. Remarkably, *VNI2*, *RNS3*, and *BFN1* have been described as prominent players in another process quite unrelated to leaf senescence: xylem vessel differentiation (Pesquet *et al.*, 2010; Yamaguchi *et al.*, 2010). The most interesting thing about the unexplored connection between both processes comes from the programmed cell death. Nonetheless, Zhong *et al.* (2010) showed that NAC transcription factors involved in secondary wall biosynthesis (SWNs) do not include ORE1 as a key player. The conclusion that can be drawn from our study and Zhong's analyses is that different processes, such as senescence and xylem vessel differentiation that

results in the up-regulation of a core set of genes, are transduced by separated pathways involving different transcription factors from the same family (the NAC family).

For the targets *BFNI* and *VNI2*, we addressed two tasks: (i) prove that *BFNI* is a direct *ORE1* target during senescence; and (ii) characterize the molecular pathway through which *ORE1* regulates *VNI2* by proposing a model of this control mechanism during senescence and of their direct interaction.

ORE1 and BFNI constitute a non-described senescence regulatory pathway in Arabidopsis

Leaf senescence undergoes three general phases: (i) the initiation phase in which chlorophyll is affected, leading to a decrease in photosynthetic activity and the transition in leaves from a nutrient sink to a nutrient source; (ii) a degenerative phase, mainly characterized by the dismantling of cellular components and their degradation; and (iii) a terminal phase, where cell integrity is lost prior to cell death and death of the whole organ (Lim *et al.*, 2003; Yoshida, 2003). During the degenerative and terminal phase, a marked decrease in total RNA levels is evident, whereas nuclear DNA is maintained to allow gene expression to continue until late in the process. The up-regulation of genes that are encoding for several nucleases has been reported, and they presumably act to degrade nucleic acids during senescence (Blank and McKeon, 1989; Buchanan-Wollaston *et al.*, 2003; Buchanan-Wollaston *et al.*, 2005; Lers *et al.*, 2001; Wood *et al.*, 1998). As we described before in the discussion, we were able to determine more than 700 up-regulated genes upon *ORE1* induction (**section 4.2.1**). The *BFNI* transcript level rapidly increased upon induction of *ORE1*, both in intact *Arabidopsis* plants and in isolated mesophyll protoplasts. In order to integrate our results, we described a hypothetical model that combines our findings with published data in which *ORE1* directly regulates *BFNI* and favors senescence and programmed cell death (PCD) in *Arabidopsis*.

Aging and a variety of environmental inputs can induce senescence. These external and internal stimuli must be integrated into the senescence signal transduction to initiate senescence syndrome. *ORE1* function as a positive regulator of leaf senescence in *Arabidopsis*, limiting the longevity of the leaf. Breeze *et al.* (2011) determined that a wide number of SAGs are under the control of *ORE1*. Thus, *ORE1* may function as an up-stream regulator in the regulatory cascade of the senescence pathway. *BFNI* was the first senescence-associated gene encoding a nuclease I enzyme as described in *Arabidopsis* (Pérez-Amador *et al.*, 2000). Despite the relevance of chlorophyll degradation as the first visible symptom during senescence, by the time yellowing of the leaf has become apparent, the majority of the senescence process has already occurred (Buchanan-Wollaston *et al.*, 2003). We determined a marked overlap in the expression patterns of *ORE1* and *BFNI-GUS* lines in advanced senescence stages (**section 5.2.1**), and we were able to identify enhanced DNase and RNase activity in protein extract from *ORE1* overexpressor lines as well as from advanced dark-induced senescence leaves

(**section 5.2.2**). Thus, we suggest that ORE1 and *BFN1* interact and exert their functions during the late degenerative and terminal phases of senescence.

Analysis of the *BFN1* promoter revealed the presence of several partial ORE1 binding sites (ORE1-BS), all of which contained the first core motif, but lacked the second core motif. Interestingly, *BFN1* promoter contains one complete ORE1-BS that differs by just one nucleotide in the second core motif to the consensus motif defined by us (**section 4.2.2**). Although punctual transversion severely affects ORE1 binding *in vitro* and *in vivo*, transcriptional activation was still observed, indicating that these partial binding sites are functional. Apparently all or at least many of the BSs present in the *BFN1* promoter are functional since the deletion promoter (190 bp) that removed all sites strongly reduced *BFN1* transactivation (**section 5.2.4**). It is plausible to think that up-regulation of *BFN1* is fundamental in the senescence progression and, therefore, must be guaranteed by having several ORE1-BSs that favor an activation, even if one of the binding sites is absent. Remarkably, the absence of ORE1-BS does not completely abolish *BFN1* expression. Nonetheless, our data strongly support that ORE1 is the most prominent direct regulator of *BFN1*, and it is likely that other TFs may bind and be co-regulators of *BFN1*. Overall, our observations confirm that, on the one hand, *BFN1* plays a pivotal role during senescence, and on the other hand, if ORE1 activation is not possible (as is the case in one promoter deletion), other TFs can activate *BFN1*, but ORE1 is the *BFN1* master regulator.

In this study, we found extended overlapping expression of *BFN1* and *ORE1* in *Arabidopsis* (**section 5.2.1**). *BFN1* is completely lost in the *anac092-1* T-DNA insertion mutant background, as shown by PCR and *BFN1* promoter-GUS reporter studies (**section 5.2.3**). The strong decrease of *BFN1* promoter expression in the *anac092-1* insertion mutant is consistent with the model that ORE1 is the master regulator of *BFN1*. Prominent expression of *BFN1* in senescence leaves, mature flowers, stigma, anthers, and the abscission zone in mature siliques agrees with the common knowledge that during senescence of floral parts, the degradation of DNA and RNA is the most common feature (Thomas *et al.*, 2003). Senescence petals of *Petunia* were found to be associated with DNA laddering and increased nuclease activity (Xu and Hanson, 2000); in senescence petals of *Ipomea*, enhanced DNA degradation, chromatin condensation, and nuclear fragmentation during PCD have been reported (Taylor *et al.*, 1993). Recently, senescence-associated RNases have also been characterized from petals of *Arabidopsis* (Taylor *et al.*, 1993) and tomato (Farage-Barhom *et al.*, 2008; Lers *et al.*, 2001).

As we described above, the up-stream regulatory pathway of *ORE1* has not been characterized extensively. *ORE1* transcript is targeted by *micro-RNA164* (*miR164*), triggering its degradation. Kim *et al.* (2009) suggested a trifurcate feed-forward regulatory pathway involving *ORE1*, *miR164*, and *EIN2* (*ethylene insensitive 2*) that ensures a robust regulation of leaf senescence and age-induced cell death. *EIN2* negatively affects *miR164* expression in an age-dependent manner, and through this allows *ORE1* mRNA to accumulate, thus acting

as a positive control element. *ORE1* and *BFN1* are highly induced during leaf senescence in the wild type mutant, but not in the *ein2* (Buchanan-Wollaston *et al.*, 2005), and it is up-regulated during pistil senescence (Carbonell-Bejerano *et al.*, 2010). We determined that the difference in *BFN1* transcript abundance between younger and older leaves was greater in *mir164abc* mutants than wild type plants (section 5.2.3). From published work, we know that *miR164* functions as a guard against premature overexpression of *ORE1*, fine-tuning senescence timing (Kim *et al.*, 2009). We identified that *BFN1* expression in the *mir164abc* triple mutant resembles exactly the age-dependent expression of *ORE1* in *mir164abc* (Kim *et al.*, 2009). Thus, we propose that the regulatory pathway that involves *ORE1*, *mir164*, and *EIN2*, and favors senescence and programmed cell death, includes the up-regulation of *BFN1* by the direct binding of *ORE1* to the *BFN1* promoter (Fig. 31).

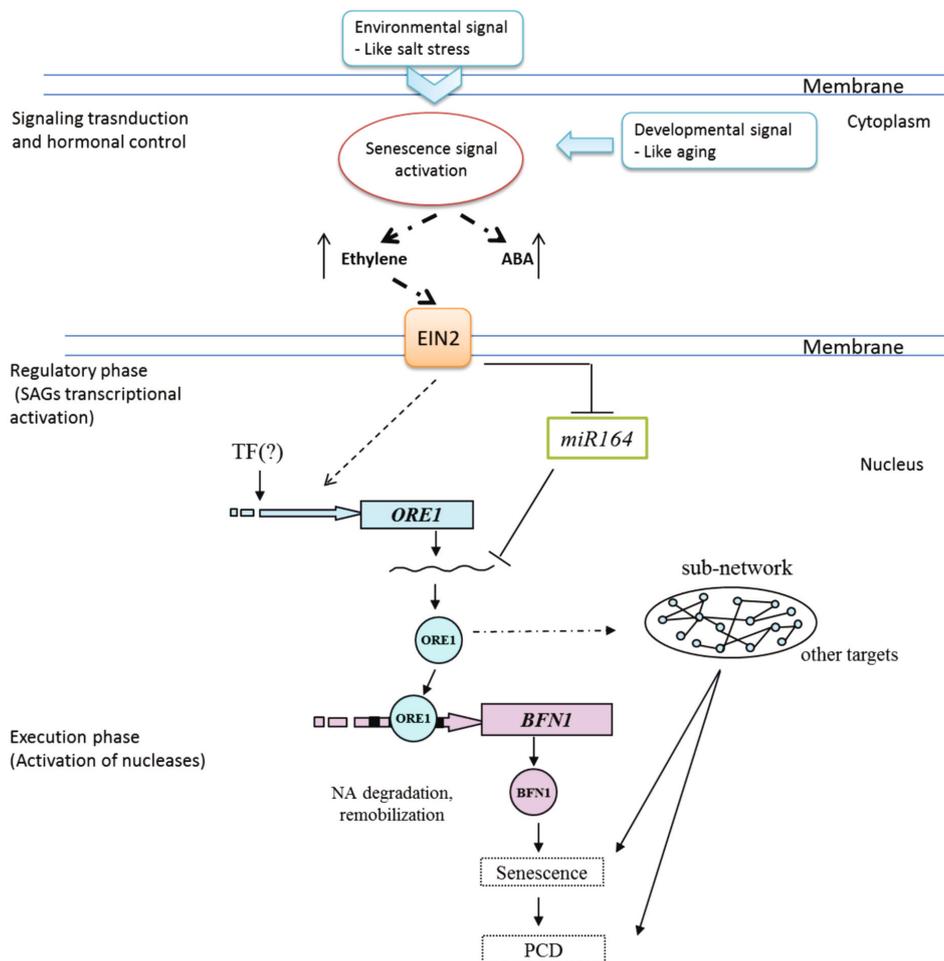

Figure 31. Hypothetical model of *ORE1* as a direct regulator of *BFN1*. Environmental and developmental signals trigger senescence syndrome, increasing ethylene and ABA levels. *ORE1* transcript is targeted by *micro-RNA164* (*miR164*), triggering its degradation and suggesting a trifurcate feed-forward regulatory pathway involving *ORE1*, *miR164*, and *EIN2* (*ethylene insensitive 2*) that ensures a robust regulation of leaf senescence and aged-induced cell death partially by the direct regulation of *BFN1*.

Abscission is an active process that occurs in different organs and regulates the detachment of organs from the main body of the plant. This process is triggered during developmental senescence and in response to environmental cues such as disease or pathogen attack (Patterson and Bleecker, 2004). The fact that *ORE1* and *BFN1* were co-expressed during flower senescence, especially in abscission zones (AZ), is a fascinating finding in our study. Taking leaf and silique senescence as an entire process, we suggest that both *ORE1* and *BFN1* may be involved not only during the progression of senescence, but as modulators in the detachment of non-functional organs in the plant. So far it is known that most genes expressed in the abscission zone do not directly affect abscission, but rather represent general housekeeping genes or genes involved in basic plant processes (Patterson and Bleecker, 2004). It is tempting to suggest that *ORE1* and *BFN1* expression are specific for the abscission process through *EIN2*. Therefore, unraveling the molecular mechanism involved represents a promising challenge.

In conclusion, our results demonstrate that senescence-induced *BFN1* expression is regulated by *ORE1*. Previous studies have demonstrated the central importance of *ORE1* for the control of leaf senescence and developmental PCD. Considering the role of *BFN1* in degradation of nucleic acids during senescence, it is reasonable to assume that *ORE1* exerts its senescence promoting function partly through *BFN1*.

Dual function of *VND Interacting2-VNI2* in developmental and induced leaf senescence in *Arabidopsis*

In **section 4.2.1**, the up-regulation of *VNI2* as a result of *ORE1* overexpression was described. Presumably, this up-regulation is at the transcriptional level and mediated by the direct interaction of *ORE1* with the *VNI2* promoter (**section 4.2.3 and 4.2.4**). The role of *VNI2* in relation to senescence has been published by Yang *et al.* (2011). In this study, controversial evidences came to light regarding the role of *VNI2* in senescence and seed germination under salt stress. Previously, it has been published that *vni2-1* shows accelerated senescence, while constitutive expression of *VNI2* leads to delayed senescence. The overall morphology and size of the full-grown transgenic plants overexpressing *VNI2* was similar to wild type plants. Moreover, bolting time was similar in wild type, *VNI2* overexpressor, and *vni2-1* mutant plants. The expression of the stress-responsive genes *COR15A*, *COR15B*, *RD29A*, and *RD29B* was up-regulated in overexpressing lines and unchanged in the *vni2-1* mutant under normal growth condition. Likewise, effects of ABA and high salinity on gene expression were significantly reduced in the *vni2-1* mutant (Yang *et al.*, 2011). The T-DNA insertion line used in this study, *vni2-2*, displays delayed senescence, delayed onset of bolting, longer and wider leaves (**section 6.2.5**), and increased salt tolerance (**section 6.2.6**). Yang *et al.* (2011) used the T-DNA insertion mutant SALK_143793, while I used GABI-KAT 799-H09. In *vni2-2*, the T-DNA insertion mutant was identified in the third exon (**section 6.2.4**), and the production of a truncated protein lacking the activation domain and the PEST motif

cannot be discarded. On the contrary, *vni2-1* insertion lies either immediately up-stream of the coding region (Yamaguchi *et al.*, 2010) or in the first intron (Yang *et al.*, 2011).

To explain the dual role of *VNI2* during leaf senescence and salt stress, the following molecular model is proposed: expression of *ORE1* that is triggered during the onset and progression of leaf senescence leads to an increase in *VNI2* transcript and favors senescence. Inducible overexpression of *VNI2* (full transcript) confirms an accelerated senescence in seedlings underlined by the dramatic up-regulation of the senescence marker *SAG12* (section 6.2.7). Nonetheless, constitutive overexpression of *VNI2* (*35S:VNI2*) leads to delayed senescence (Yang *et al.*, 2011), more likely due to an unknown transcriptional regulatory loop that may lead to an increased mRNA turnover (Hypothesis 1) (Fig. 32). Seedling inducible overexpressing *VNI2* (*VNI2-IOE*-lines) exhibited a slight reduction in size, whereas seedling inducible overexpressing truncated *VNI2* (*VNI2-ΔC-IOE*-lines) was severely affected and exhibited a dwarfed, yellowish phenotype (section 6.2.7).

According to Yamaguchi *et al.* (2010), a C-terminal truncated *VNI2* is more stable than the full-length protein, and the overexpression of a truncated *VNI2* protein effectively causes a vessel defect. Thus, it is plausible to think that the marked reduction in size observed in the *VNI2-ΔC-IOE* seedlings is caused by severe defects in root vessel formation. Microscopic analyses of these lines are required to confirm this assertion. The inducible overexpression of *VNI2-ΔC-IOE* results in higher levels of mRNA (tested by qRT-PCR) than the inducible over-expression of the full transcript (*VNI2-IOE*) (section 6.2.7). Moreover, seedlings that were overexpressing a truncated version of *VNI2* exhibited higher levels of *SAG12* compared to wild type, but a marked decrease compared to seedlings that were overexpressing a full *VNI2* transcript, suggesting a delay in senescence. Strikingly, *vni2-2* also displays a delayed senescence phenotype, along with a delayed onset of bolting and an apparent increase in biomass, represented by bigger leaves (section 6.2.7). Likely, *vni2-2* is able to produce a truncated protein that comprises only the NAC domain which has been characterized to be a transcriptional repressor under normal growth condition and a transcriptional activator under salt stress (Yamaguchi *et al.*, 2010; Yang *et al.*, 2011). It is feasible to think that this protein is, in fact, produced *in planta* since a screening of databases revealed that an alternative splicing (AS) form of *VNI2* has been reported (Iida *et al.*, 2009) (Hypothesis 2) (Fig. 32). Ostensibly, an uncharacterized switch is activated during salt stress and also if *VNI2* is constitutively overexpressed which, in turn, promotes the expression of stress responsive genes, such as *COR15A/B* and *RD29A/B*, and represses the expression of genes involved in senescence progression (such as *SAG12*), thus enhancing salt and cold resistance (Yang *et al.*, 2011). The delayed senescence phenotype observed in seedling inducible overexpressing truncated *VNI2* and in the *vni2-2* mutant, as well as the enhanced salt resistance displayed by the *vni2-2* mutants, might be associated with the same mechanism. It is feasible to assume that the switch is transcriptional and post-transcriptional, and it may likely influence both mRNA and protein stability (Hypothesis 3) (Fig. 32).

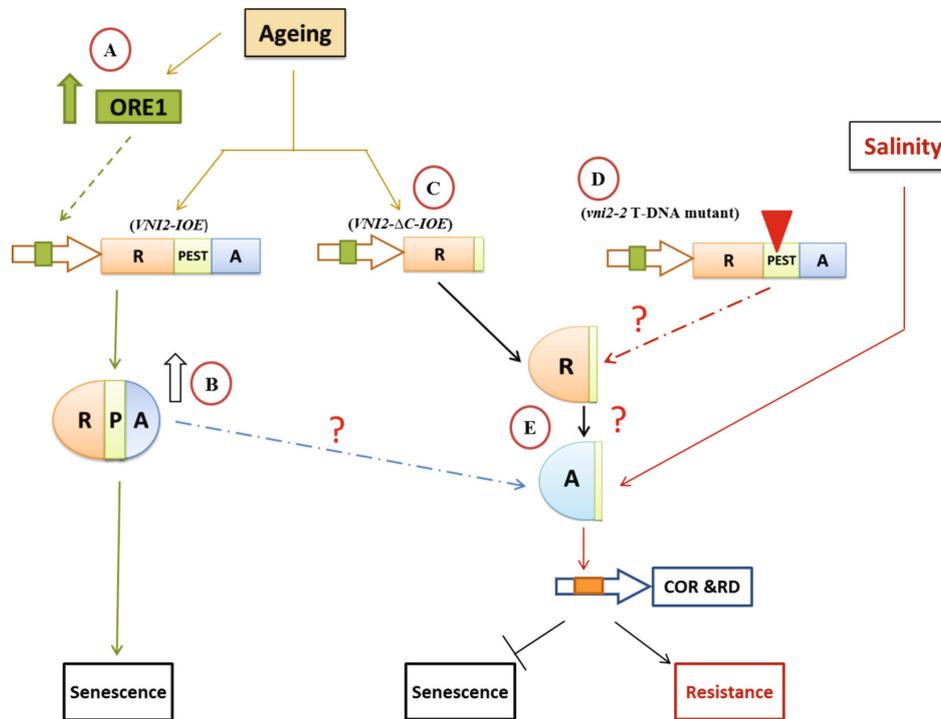

Figure 32. Molecular model of VNI2 dual role during developmental and salt-induced leaf senescence. Hypothesis 1. (A). Overexpression of ORE1 leads to an increase of *VNI2*, probably by direct binding of ORE1 to the *VNI2* promoter. (B). *VNI2* protein has a conserved NAC domain in the N-terminal region described as a repressor (R). The C-terminal region has a characterized activator domain (A) and a PEST motif (P) that regulates protein stability. Inducible overexpression of *VNI2* (*VNI2-IOE*) leads to up-regulation of *SAG12*, suggesting that ORE1 and *VNI2* integrate a regulatory pathway that positively controls developmental senescence. **Hypothesis 2.** (C). Overexpressing of a truncated *VNI2* protein *VNI2-DC-IOE* (lacking half P and A) leads to delayed senescence. **Hypothesis 3.** (D). *vni2-2* likely produces a truncated protein (lacking half P and A) and exhibits delayed senescence. (E). *VNI2* acts as activator and repress senescence, and it induces resistance under salt stress by up-regulation of COR/RD genes. Presumably, this role is controlled by uncharacterized mechanisms involving post-transcriptional and/or post-translational changes.

The evidence obtained from this study, along with available public data, suggests a connection between *ATAF1*, *ORE1*, and *VNI2* during senescence. Therefore, the following model (**Fig. 33**) is proposed, and it integrates these senescence NAC TFs (senNAC TF) into the senescence regulatory pathway. The model considers the dual role of *VNI2* during developmental and induced leaf senescence, and it describes two regulatory pathways that positively/negatively regulate senescence. *ORE1* and *VNI2* mRNA expression are positively and significantly regulated by *ATAF1*. Both promoters are transactivated by *ATAF1* (**section 2.2.5** and **section 6.2.8**), but transactivation of the *VNI2* promoter occurs even in the absent of *ORE1*, suggesting that *ATAF1* might exert its regulatory function directly on *VNI2* and/or *ORE1* (**section 6.2.8**). We determined that overexpression of a CDPK named CKOR (calcium-dependent kinase regulating *ORE1*) *in vivo* leads to an increase in the transcriptional activity of *VNI2*, and apparently *VNI2* requires a considerable accumulation of phosphorylated *ORE1* protein to be activated (**Chapter 3**). This is likely the phosphorylated *ORE1* that binds to one (or more)

ORE1-BS (binding site) present in the *VNI2* promoter and then proceeds with senescence. Based on experimental data using knockout and *VNI2* overexpressor lines, it can be speculated that under the control of an uncharacterized post-transcriptional/post-translational mechanism, *VNI2* can turn from a transcriptional repressor to an activator. This likely involves the production of two *VNI2* splicing forms; one that generates a full protein (showing an increased proteasome-mediated proteolysis), and a more stable truncated *VNI2* mRNA whose protein lacks the PEST motif and the activator domain. During developmental leaf senescence, *VNI2* up-regulation may lead to the repression of a set of genes that prevent senescence, most likely *COR/RD* genes. As we described above, there is evidence that the constitutive overexpression of *VNI2* delays senescence and increases salt resistance (Yang *et al.*, 2011), whereas inducible overexpression of *VNI2* has the opposite effect on seedlings growing in estradiol. Moreover, the *vni2-2* T-DNA insertion mutant (T-DNA insertion in the third exon) and an inducible overexpressor line carrying a truncated version of *VNI2* (producing a protein lacking part of the third exon) exhibited a prolonged life span and enhanced salt tolerance, presumably due to the expression of a *VNI2* that harbors the NAC domain and lacks the PEST motif as well as the activation domain located in the N-terminal region.

It is well established that *ATAF1*, *ORE1*, and *VNI2* are highly induced by salt stress and ABA (Balazadeh *et al.*, 2010a,b; He *et al.*, 2005; Lu *et al.*, 2007; Yang *et al.*, 2011). According to published data, in the case of *ATAF1*, the induction in response to drought salinity is achieved in an ABA-independent manner, even though ABA alone is able to induce *ATAF1* expression (Wu *et al.*, 2009). Under short-term salt stress (two hours of treatment), plants overexpressing *ATAF1* showed down-regulation of three *COLD-REGULATED (COR)* and *RESPONSIVE TO DEHYDRATION (RD)* genes (*RD22*, *RD29A*, and *COR47*). Interestingly, these transcripts were slightly up-regulated in the same line of plants after long-term salt stress (10 hours). Authors suggested that there should be a feedback regulation of those genes affected by *ATAF1* under salt stress (Wu *et al.*, 2009). In addition, *VNI2* has been reported to integrate ABA-mediated abiotic stress signals into leaf aging by regulating a subset of *COR/RD* genes. Constitutive overexpression of *VNI2* leads to an up-regulation of *COR15A/B* and *RD29A/B*. The expression of these genes was unchanged in *vni2-1* mutants under normal growth conditions and significantly reduced under ABA and high salinity. Notably, *VNI2* behaves like a transcriptional activator under high salinity. To explain these observations, the authors suggest that high salinity may induce structural and/or activity changes of *VNI2* (Yang *et al.*, 2011). All observations strongly support the existence of an uncharacterized mechanism that regulates the transcriptional activity of *VNI2*. The novelty is that such a mechanism has not yet been elucidated for any senNAC TFs. The challenge is to determine if it is a structural change or a post-transcriptional/post-translational regulatory loop that results in turning *VNI2* from a transcriptional repressor to a transcriptional activator. Nevertheless, salt stress and ABA seem to be master input signals for the regulatory pathway that integrates *ATAF1*, *ORE1*, and *VNI2* during developmental and induced leaf senescence (Fig. 33).

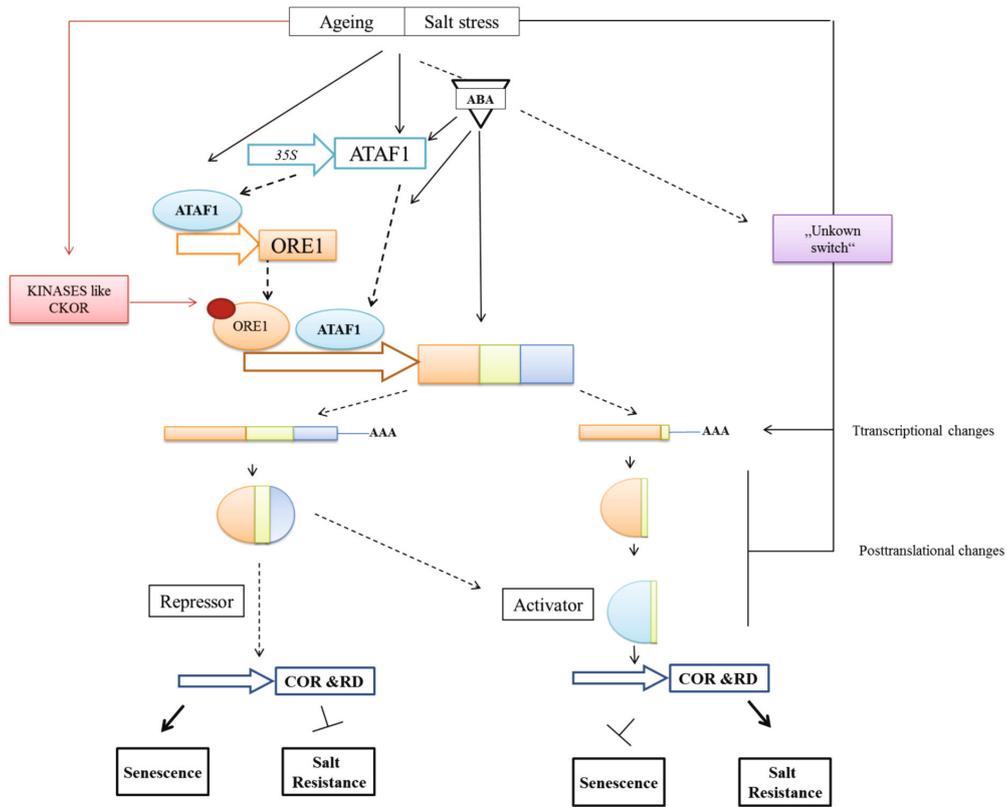

Figure 33. Model of *ATAF1*, *ORE1*, and *VNI2* in the regulation of developmental and induced leaf senescence. 1. *ATAF1* is able to regulate expression of *ORE1* and *VNI2*. Aging activates the expression of CKOR that regulates *ORE1* and favors the transcriptional activation of *VNI2*. An uncharacterized switch controls post-transcriptional and/or post-translational changes in *VNI2*. Progression of senescence might be regulated by a full version of *VNI2* that represses the expression of *COR/RD* genes. It is likely another version of *VNI2* is produced or activated under certain conditions and involves the activator domain and the PEST motif present in the C-terminal region of *VNI2*. Delayed senescence and enhanced salt resistance may be achieved through the production of *VNI2* which lacks the activator domain and the PEST motif.

Future challenges and outlook

This PhD focused in unraveling the ORE1 regulon, elucidating up- and down-stream components. Substantial evidences were obtained that demonstrate the role of ORE1 as a TF that positively regulates the expression of more than 700 genes related to the senescence syndrome. A set of 17 genes were identified as putatively regulated by a direct interaction with ORE1. The interaction of ORE1 with the promoter region of some targets was tested *in vitro* and *in vivo*. Furthermore, the direct regulation of *BFN1* by *ORE1* during senescence was probed and important evidences that suggest *VNI2* and *RNS3* as putative direct targets of ORE1 were collected. Nevertheless, this knowledge is only the starting point to suggest conclusive models about the exact mode of interaction of ORE1 during developmental and induced leaf senescence with these targets. Therefore, here further experiments are proposed with the aim to elucidate the signal transduction cascades activated by ORE1. For a better view of the future challenges, the following work packages are suggested (WP):

WP1: Extension of the ORE1 up-stream regulatory pathway

As described in **Chapter 2** the up-stream regulatory pathway of *ORE1* still poorly characterized. Therefore, the novel discover of ATAF1 and CKOR as possible regulators of ORE1 provide a good starting point for further studies. It is necessary to confirm if the senNAC TF ATAF1 and the calcium-dependent protein kinase CKOR control ORE1 and favors senescence in *Arabidopsis*. Using chromatin immunoprecipitation (ChIP) coupled with deep-sequencing or tiling arrays (ChIP-CHIP) employing transgenic plants expressing ATAF1-GFP and/or ATAF1-Halotag fusion proteins, will help to confirm the direct binding of ATAF1 to *ORE1* promoter and maybe to the promoter regions of some ORE1 putative targets like *VNI2* *in vivo*. These results will help to clarify not only if ATAF1 binds directly to *ORE1* promoter but also which ORE1 putative targets may also be regulated by ATAF1. This work will allow to define up to which point there is a redundancy between ATAF1 and ORE1 during senescence. It would be of great advantage implementing promoter arrays to identify sequences bound by all three senNAC TFs that are of primary interest after this study. Also, yeast one-hybrid experiments can be used to identify TFs that bind specifically to the *ORE1* promoter. Due to the important role of *ATAF1* and *ORE1* in salt stress responses and the dual role of *VNI2* upon salt stress, transactivation assays that includes a phase of salt

stress will give insights into a possible cross-talk between these three senNAC TFs during developmental and salt- induced leaf senescence.

Previous phosphoproteomic approach using a CKOR overexpressor lines revealed ORE1 as one of the few proteins differentially phosphorylated. We determine that *BFN1*, *VNI2* and *RNS3* promoter transactivation was enhanced in presence of overexpression of CKOR in wild type protoplast (**Chapter 3**). The extent and dynamic changes in ORE1 phosphorylation have not been studied. As a baseline for these future studies, firstly a series of transactivation assays using protoplasts that lack the expression of ORE1 compared to transactivation of promoter regions in protoplasts that overexpress ORE1 will be required. Secondly, affinity chromatography will be used to purify/enrich phosphorylated ORE1 to identify the sites phosphorylated using high-accuracy mass spectrometry. Thirdly, the physiological characterization of CKOR transgenic lines and the phenotypic characteristics of such lines will provide information if they exhibit a particular developmental senescence phenotype or particular resistance to abiotic stresses such as salt and cold stress.

ORE1 promoter deletion analysis gave the first insights to generate the hypothesis that the 5'UTR-Py-rich motifs are related to ORE1 senescence-specific expression patterns. Additional experiments are required to confirm that the 5'UTR in general and both motifs in particular are the important motifs and if their absence causes a loss of promoter-driven GUS activity or if our observations are purely an artifact due to the shortening of the promoter that renders an unspecific weakened signal. Thus, mutations of this specific motifs as well as substitution of the ORE1 5'UTR for a conventional 5'UTR will clarify the role of this region in *ORE1* promoter activity related to the senescence syndrome.

WP2: Analysis of the role of ORE1 during germination and abscission

Two interesting findings of this work were related to the marked and rapid promoter expression of *ORE1* in mature embryos and abscission zones in mature siliques in *Arabidopsis* (**Chapter 2 and Chapter 4**). Some recent studies suggested the possible role of *ORE1* as a regulator during embryo and seed development (Fait *et al.*, 2011) and *anac092-1* T-DNA insertion mutant was reported to have a delayed flowering phenotype (AL-Daoud and Cameron, 2011). Nevertheless, these are unexplored facets of ORE1 and therefore there is not available data yet. The characterization of expression patterns during embryo development and seed maturation are required to shed light on the role of ORE1 in both processes. One significant contribution to understand the role of ORE1 during abscission will be gain by the identification and characterization of *anac092-1* T-DNA insertion mutant pattern during abscission. It is feasible that the *anac092-1* T-DNA insertion mutant reveals as a delayed abscission mutant.

WP3: Determination of the dual role of VNI2 during senescence

The novel finding of VNI2 as a possible NAC TF that has (i) a dual role as activator or repressor of senescence (**Chapter 6**) and (ii) a mutant that exhibits a prolonged life span, delayed onset of bolting, higher salt stress tolerance and a presumable increase on biomass open a complete new research on this NAC TF. Firstly, a confirmation of the production of a truncated VNI2 protein in *vni2-2* T-DNA insertion mutant is required using for instance Western blots. The complete characterization if the presumable increase on biomass really takes place is also required.

The role of the PEST-motif in regulating the stability of the protein has already been studied (Yamaguchi *et al.*, 2010) using proteasome inhibitors. Nevertheless, we found that the inducible overexpression of a full or truncated version of *VNI2* (with or lacking the PEST motif) result also in differences at the transcriptional level (**section 6.2.7**). Clearly the transcript corresponding to the truncated protein was strongly overexpressed as the transcript corresponding to the full version. This unexpected and exciting discovery may indicate that VNI2 stability is regulated both at the transcriptional as well as at the post-transcriptional level. To really differentiate if the overexpression of a shorter transcript (lacking the PEST motif and the activation domain) leads to a higher production of mRNA or simply to a longer half-life of the mRNA, experiments using the widely known inhibitor of transcription Actinomycin D are required.

The base of our work to identify target genes regulated by ORE1 relies on the use of Affymetrix chip arrays. The prominent role of microRNAs in the regulation of ORE1 is known (Kim *et al.*, 2009) and evidently at least ATH1 Affymetrix chips do not consider this level of regulation, since no microRNA is represented in this chip. In order to extend our knowledge and measure transcript levels using an unbiased method that allows us the identification of all kinds of RNAs present in a particular line/cell/condition including mRNAs, non-coding RNAs and small RNAs new technologies must be implemented for the analysis of TFs in our group. RNA-Seq a transcriptome profiling approach based on deep-sequencing technologies offers itself as the most promising tool to acquire more precise measurements of transcript levels and their isoforms. The implementation of this technology is of particular interest for the analysis of VNI2 to establish with certainty if indeed this senNAC TF may be regulated at the transcriptional level by alternative splicing.

And last but not least, the knowledge gain in our transcriptome profiling assays, functional and molecular characterization of transgenic lines and *in vivo*, *in vitro* and *in silico* analysis of promoters need to be integrated to allow the reconstruction of the gene regulatory networks (GRN) during developmental and salt induced senescence. The reconstruction of the GRN that joins ATAF1, ORE1 and VNI2 will serve not only to complete our knowledge on onset and progression of developmental and induced senescence, but also will allow us to predict new components and regulatory mechanisms that may remain unforeseen if the current knowledge is not combined to make use of the advantages of computer modeling.

Annex 1

List of oligonucleotides used in this study

VN12 Primers			
Internal code	Direction	Sequences of the oligonucleotides (5'-3')	Purpose
133	F	<u>GGATCCAATTACTCAGAGTTCCATA</u>	Amplification of VN12 (1570 bp) promoter. <i>Bam</i> HI restriction site underlined
135	F	<u>GGATCCACATGAAGCAAGCAAAAT</u>	Amplification of VN12 (571 bp) promoter. <i>Bam</i> HI restriction site underlined
134	R	<u>CCATGGGGTGGTTCCAAACAAG</u>	Amplification of VN12 (571 bp) promoter. <i>Nco</i> I restriction site underlined
142	F	<u>CTCGAGATGGATAATGTCAAACCTTGTTAAG</u>	Amplification of VN12 CDS. <i>Xho</i> I restriction site underlined
201	R	<u>ACTAGTTCATCTGAAACTATTGCAACTAC</u>	Amplification of VN12 CDS. <i>Spe</i> I restriction site underlined
141	R	<u>ACTAGTTCACGGCAAAAAGTTCAAATCTGTTG</u>	Amplification of VN12 CDS. <i>Spe</i> I restriction site underlined
149	F	<u>GGATTTACCTGGCAATTTGGAG</u>	To determined transcript abundance (VN12 first exon)
150	R	<u>AATAACCCAGACCCAGTTGCC</u>	To determined transcript abundance (VN12 first exon)
70	F	<u>CAAAGGCAAAACCCACCTCATGGC</u>	To determined transcript abundance (VN12 second exon)
71	R	<u>CTGAGTGGGACCCCATAGAACTCG</u>	To determined transcript abundance (VN12 second exon)
160	F	<u>CAGATTT GAACCTTTTGGCCGAG</u>	To determined transcript abundance (VN12 third exon)
161	R	<u>GTCGTGACTCCACTTGAAGCAT</u>	To determined transcript abundance (VN12 third exon)
131	F	<u>GAGATTGCCACCTGGATTCTAG</u>	Confirmation homozygosity T-DNA insertion line
132	R	<u>GAAGAAATTGAAATTCGCTAGAGAA</u>	Confirmation homozygosity T-DNA insertion line
158	R	<u>CCCATTTGGACGTGAATGTAGACAC</u>	Confirmation homozygosity T-DNA insertion line

Annex 2

ORE1-BS (Binding Sites) present in the up-stream region of ORE1-putative target genes. Positions are on relation to the ATG (first nucleotide up-stream is -1). Size of the upstream regions *BFN1* 1084 bp, *VNI2* 1571 bp, *RNS3* 1062 bp, *ORE1* 1281 bp, *SINA1* 1018 bp, *SAG29* 831 bp. Bold letters indicate ORE1-BSs tested by EMSA. The program fuzznuc from EMBOSS was used to detect ORE1-BSs (Rice *et al.* 2000). Underlined letter in the *BFN1* promoter (position -196) indicates one nucleotide difference from the consensus ORE1-BS.

Annex 4

Expression of 269 genes differentially expressed after five hours estradiol induction. 195 genes were found up- and 74 down-regulated up regulated (Affymetrix data). Data are means of three replicates. Bold letters indicate the selected putative ORE1 targets. (*) Transcription factors.

Annex 5

Expression of 643 up-regulated and 188 down-regulated genes (two-fold cut-off) upon transient overexpression of ORE1 in mesophyll cell protoplast (ATH1 Affymetrix Array). Data are means of two replicates. Bold letters indicate the selected putative ORE1 targets. (*) Transcription factors.

AT5G17760	AAA-type ATPase family protein	250062_at	-1,029

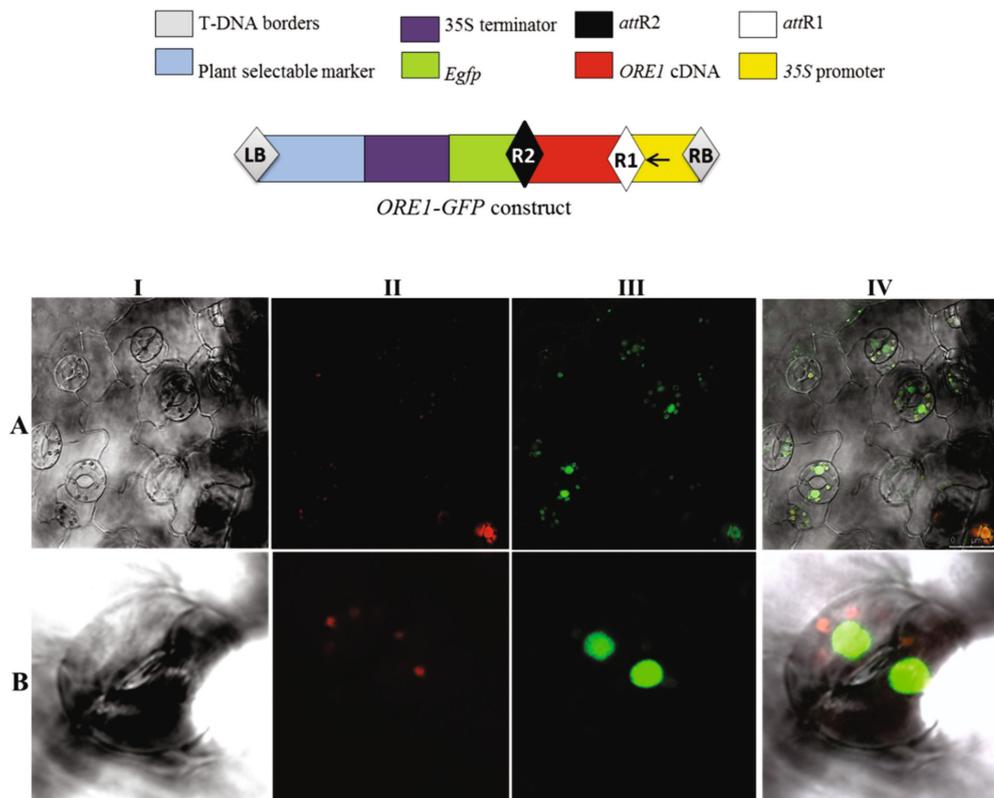

AGI Identifier	Description	Affymetrix ID	Log2 Fch
AT5G18170	GDH1 (GLUTAMATE DEHYDROGENASE 1); oxidoreductase	250032_at	-1,002
AT5G18290	SIP1;2 (SMALL AND BASIC INTRINSIC PROTEIN1B)	250025_at	-1,203
AT5G18500	protein kinase family protein	249985_at	-1,027
AT5G19140	auxin/aluminum-responsive protein, putative	249922_at	-1,146
AT5G22860	serine carboxypeptidase S28 family protein	249860_at	-1,708
AT5G25170	similar to unknown protein [<i>Arabidopsis thaliana</i>]	246931_at	-1,297
AT5G38870		249505_at	-1,459
AT5G39090	transferase family protein	249489_at	-1,463
AT5G41610	[AT5G41610, ATCHX18 (cation/hydrogen exchanger 18); monovalent cation:proton antiporter]	249255_at	-1,109
AT5G42060	similar to unknown protein [<i>Arabidopsis thaliana</i>] (TAIR:AT1G64490.1)	249253_at	-1,118
AT5G42250	alcohol dehydrogenase, putative	249242_at	-1,278
AT5G44580	similar to unknown protein [<i>Arabidopsis thaliana</i>]	249010_at	-1,291
AT5G47220	ATERF-2/ATERF2/ERF2 (ETHYLENE RESPONSE FACTOR 2); DNA binding / transcription factor/ transcriptional activator	248794_at	-1,317
AT5G47230	ERF5 (ETHYLENE RESPONSIVE ELEMENT BINDING FACTOR 5); DNA binding / transcription factor/ transcriptional activator	248799_at	-1,185
AT5G49230	HRB1 (HYPERSENSITIVE TO RED AND BLUE)	248595_at	-1,037
AT5G52380	zinc knuckle (CCHC-type) family protein	248357_at	-1,229
AT5G55120	similar to VTC2 (VITAMIN C DEFECTIVE 2) [<i>Arabidopsis thaliana</i>] (TAIR:AT4G26850.1)	248091_at	-1,071
AT5G57220	CYP81F2 (cytochrome P450, family 81, subfamily F, polypeptide 2); oxygen binding	247949_at	-1,253
AT5G57655	xylose isomerase family protein	247924_at	-1,172
AT5G59530	2-oxoglutarate-dependent dioxygenase, putative	247729_at	-1,333
AT5G59700	protein kinase, putative	247686_at	-1,149
AT5G61380	TOC1 (TIMING OF CAB 1); transcription regulator	247525_at	-1,110
AT5G62730	proton-dependent oligopeptide transport (POT) family protein	247447_at	-1,100
AT5G64890	PROPEP2 (Elicitor peptide 2, precursor)	247205_at	-1,498
AT5G64905	PROPEP3 (Elicitor peptide 3, precursor)	247215_at	-1,286
AT5G65240	leucine-rich repeat family protein / protein kinase family protein	247197_at	-1,150
AT5G65600	legume lectin family protein / protein kinase family protein	247145_at	-1,002
AT5G66530	aldose 1-epimerase family protein	247101_at	-1,169
AT5G67080	MAPKKK19 (Mitogen-activated protein kinase kinase kinase 19); kinase	247026_at	-1,049

Annex 6

Subcellular localization of ORE1-GFP fusion protein in *Arabidopsis*

Upper panel: *ORE1* cDNA was amplified using a combination of primer forward and reverse (123-124 respectively) (**Annex 1**) and then cloned into the Gateway pENTR-D-TOPO entry vector. The entry vector construct was recombined into Gateway destination vector *pK7FWG2.0* (Karimi *et al.* 2002) using the LR reaction mix II (Invitrogen) to obtain the final reporter vector *ORE1-GFP*. The recombination reactions were done according with the manufacturer's instructions (Invitrogen).

Bottom panel: The p35S-driven *ORE1-GFP* fusion protein was expressed in wild type (Col-0) after *Agrobacterium*-mediated transformation as described in **section 2.4.4** and viewed under fluorescence light using a confocal laser scanning microscopy (LSCM) SP5, Leica with software LAS AF (Leica). **(I)** is shown in bright field **(II)** shows the red autofluorescence of chlorophyll, **(III)** the GFP-signal, and **(IV)** the merged signals. **(A)** The image shows an overview of epidermal cells, guard cells and stomata from a leaf of 15-day-old *Arabidopsis* seedling. Seedlings were grown in MS media as described in **section 2.4.2**. **(B)** Close-up of a pair of guard cells forming the stoma. *ORE1-GFP* protein is expressed in nucleus. Chloroplasts are visible in guard cells fluorescing red.

Allgemeinverständliche Zusammenfassung

Der Alterungsprozess lebender Organismen wird seit vielen Jahren wissenschaftlich untersucht. In Pflanzen wird der Alterungsprozess Seneszenz genannt. Er ist für das Überleben der Pflanze von großer Bedeutung. Dennoch ist unser Wissen über die molekularen Mechanismen der Blattseneszenz, dessen komplexe Steuerung und die Wechselwirkungen mit Umweltsignale noch sehr limitiert. Ein wichtiges Steuerungselement besteht in der Aktivierung bestimmter Transkriptionsfaktoren (TFs) die während der Seneszenz unterschiedlich exprimiert werden. Aus der Literatur ist bekannt, dass Mitglieder der NAC TF Familie (*NAM/ATAF/CUC*) an der Regulation der Seneszenz bei Pflanzen beteiligt sind. ORE1 (*ANAC092/AtNAC2*), ein NAC TF mit erhöhter Genexpression während der Seneszenz, wurde erstmals in Mutanten mit verzögerte Seneszenz beschrieben, die molekularen Mechanismen, wie ORE1 die Seneszenz kontrolliert und die Stoffwechselwege reguliert, sind aber noch weitgehend unbekannt.

Die Arbeiten im Rahmen dieser Dissertation wurden durchgeführt, um einen tieferen Einblick in die Regulationsmechanismen von ORE1 auf natürliche, dunkel induzierte sowie Salzstress-induzierte Seneszenz zu erhalten. Ergebnisse von Untersuchungen an zwei unterschiedlichen Pflanzenspezies (*Arabidopsis thaliana* und *Nicotiana tabacum*) deuten auf ein ähnliches Expressionsmuster von ORE1 während der natürlichen als auch der Salz-induzierten Seneszenz hin. In der Promotorregion von ORE1 wurde ein für natürliche Seneszenz charakteristisches Muster identifiziert. In vivo Analysen ergaben darüber hinaus Hinweise auf zwei weitere ORE1 Regulatoren. Debei handelt es sich umeinen weiteren NAC TF (*ATAF1*) und (ii) CKOR, einer Calcium-abhängige Protein-Kinase (CDPK). In weiteren Studien wurden sechs Gene identifiziert, die durch ORE1 reguliert werden. In den Promotoren dieser Gene wurden entsprechende Bindestellen für ORE1 lokalisiert. Die ORE1-Bindung an die Promotoren wurde daraufhin sowohl in vitro als auch in vivo verifiziert. Zwei dieser Gene, die *BIFUNCTIONAL Nuclease 1 (BFNI)* und *VND-Interacting2 (VNI2)*, wurden zudem auf molekularer und physiologischer Ebene untersucht.

Lilian Paola Matallana-Ramírez

Contact information matallana@mpimp-golm.mpg.de – lilianmatallana@gmail.com

Personal information Nationality Colombian
Place of Birth Bogotá D.C
Date of Birth 31.03.1980

Research interests Plant physiology, *in vitro* culture and micropropagation of tropical fruits crops, transcriptional regulation.

Education **University of Potsdam**, Potsdam, Germany
Department of Molecular Biology
Ph.D Student (2008-2012)

- Dissertation Topic: Unraveling the ORE1 Regulon in *Arabidopsis thaliana*: Molecular and Functional Characterization of Up- and Down-stream Components
- Supervisors: Prof. Dr. Bernd Mueller-Roeber and Dr. Salma Balazadeh

Universidad Nacional de Colombia, Bogotá D.C., Colombia
Department of Biology
Biologist, July 2006 (Equivalent to the German “Diplome Biologie”)

- Dissertation Topic: Standardization of *in vitro* protocol in *Tropaeolum majus* (*Tropaeolaceae*) for development its morphogenic potential
- Supervisors: Prof. Dr. Margarita Perea-Dallos
- Grade: (5.0/5.0 maximum grade)

Honors and Awards DAAD complete fellowship for Ph.D. project (2008-2012). Potsdam University and Max Planck Institute for Plant Molecular Physiology. Potsdam-Germany.

Mariano Ospina-Perez Prize 2010. Special Mention: Contribution to the sustainable development of Colombia for the work and publication: Biotechnology applied to tropical fruit crops improvement. Bogotá-Colombia.

Erklärung

Hiermit erkläre ich, dass ich die vorliegende Arbeit selbständig und unter Verwendung keiner anderen als den von mir angegebenen Quellen und Hilfsmitteln verfasst habe.

Ferner erkläre ich, dass ich bisher weder an der Universität Potsdam noch anderweitig versucht habe, eine Dissertation einzureichen oder mich einer Doktorprüfung zu unterziehen.
