## Abstract

Climate is the principal driving force of hydrological extremes like floods and attributing generating mechanisms is an essential prerequisite for understanding past, present, and future flood variability. Successively enhanced radiative forcing under global warming enhances atmospheric water-holding capacity and is expected to increase the likelihood of strong floods. In addition, natural climate variability affects the frequency and magnitude of these events on annual to millennial time-scales. Particularly in the mid-latitudes of the Northern Hemisphere, correlations between meteorological variables and hydrological indices suggest significant effects of changing climate boundary conditions on floods. To date, however, understanding of flood responses to changing climate boundary conditions is limited due to the scarcity of hydrological data in space and time. Exploring paleoclimate archives like annually laminated (varved) lake sediments allows to fill this gap in knowledge offering precise dated time-series of flood variability for millennia. During river floods, detrital catchment material is eroded and transported in suspension by fluid turbulence into downstream lakes. In the water body the transport capacity of the inflowing turbidity current successively diminishes leading to the deposition of detrital layers on the lake floor. Intercalated into annual laminations these detrital layers can be dated down to seasonal resolution.

Microfacies analyses and X-ray fluorescence scanning ( $\mu$ -XRF) at 200  $\mu\text{m}$  resolution were conducted on the varved Mid- to Late Holocene interval of two sediment profiles from pre-alpine Lake Ammersee (southern Germany) located in a proximal (AS10<sub>prox</sub>) and distal (AS10<sub>dist</sub>) position towards the main tributary River Ammer. To shed light on sediment distribution within the lake, particular emphasis was (1) the detection of intercalated detrital layers and their micro-sedimentological features, and (2) intra-basin correlation of these deposits. Detrital layers were dated down to the season by microscopic varve counting and determination of the microstratigraphic position within a varve. The resulting chronology is verified by accelerator mass spectrometry (AMS)  $^{14}\text{C}$  dating of 14 terrestrial plant macrofossils.

Since ~5500 varve years before present (vyr BP), in total 1573 detrital layers were detected in either one or both of the investigated sediment profiles. Based on their microfacies, geochemistry, and proximal-distal deposition pattern, detrital layers were interpreted as River Ammer flood deposits. Calibration of the flood layer record using instrumental daily River

Ammer runoff data from AD 1926 to 1999 proves the flood layer succession to represent a significant time-series of major River Ammer floods in spring and summer, the flood season in the Ammersee region.

Flood layer frequency trends are in agreement with decadal variations of the East Atlantic-Western Russia (EA-WR) atmospheric pattern back to 200 yr BP (end of the used atmospheric data) and solar activity back to 5500 vyr BP. Enhanced flood frequency corresponds to the negative EA-WR phase and reduced solar activity. These common links point to a central role of varying large-scale atmospheric circulation over Europe for flood frequency in the Ammersee region and suggest that these atmospheric variations, in turn, are likely modified by solar variability during the past 5500 years.

Furthermore, the flood layer record indicates three shifts in mean layer thickness and frequency of different manifestation in both sediment profiles at ~5500, ~2800, and ~500 vyr BP. Combining information from both sediment profiles enabled to interpret these shifts in terms of stepwise increases in mean flood intensity. Likely triggers of these shifts are gradual reduction of Northern Hemisphere orbital summer forcing and long-term solar activity minima. Hypothesized atmospheric response to this forcing is hemispheric cooling that enhances equator-to-pole temperature gradients and potential energy in the troposphere. This energy is transferred into stronger westerly cyclones, more extreme precipitation, and intensified floods at Lake Ammersee.

Interpretation of flood layer frequency and thickness data in combination with reanalysis models and time-series analysis allowed to reconstruct the flood history and to decipher flood triggering climate mechanisms in the Ammersee region throughout the past 5500 years. Flood frequency and intensity are not stationary, but influenced by multi-causal climate forcing of large-scale atmospheric modes on time-scales from years to millennia. These results challenge future projections that propose an increase in floods when Earth warms based only on the assumption of an enhanced hydrological cycle.

## Zusammenfassung

Globale Klimamodelle prognostizieren eine Zunahme von Starkhochwassern aufgrund eines intensivierten hydrologischen Kreislaufs infolge der Klimaerwärmung. Weiterhin werden natürliche Klimafaktoren wie solare Aktivität, explosiver Vulkanismus, Meereis, atmosphärische und ozeanische Zirkulation, die Intensität und Häufigkeit solcher Ereignisse auf Zeitskalen von Jahren bis Jahrtausenden beeinflussen. Für ein umfassendes Verständnis hochwassergenerierender Klimamechanismen müssen daher lange Zeiträume und regionale Muster in Betracht gezogen werden. Aufgrund der Limitierung der meisten instrumentellen Abflusszeitreihen auf die letzten 100 Jahre, bieten diese allerdings nur einen sehr begrenzten Einblick in das Spektrum möglicher Klima-Hochwasser Zusammenhänge.

Die Nutzung natürlicher Hochwasserarchive, wie jährlich laminiertes (warvierter) Seesedimente, erlaubt die Untersuchung von Hochwasseraktivität auf Zeitskalen von Jahrtausenden und damit in unterschiedlichen Klimaszenarien, wie der Kleinen Eiszeit und der Mittelalterlichen Wärmeperiode auf Basis präziser Chronologien. Durch Hochwasser in einen See eingetragenes detritisches Material aus dem Einzugsgebiet bildet, eingeschaltet in den jährlichen Sedimentationszyklus, eine charakteristische Abfolge von Hochwasserlagen auf dem Seeboden. Das Zählen jährlicher Laminierungen und die Position innerhalb eines jährlichen Sedimentationszyklus ermöglichen die Datierung einzelner Hochwasserlagen mit bis zu saisonaler Genauigkeit.

Der Ammersee im Alpenvorland bildet ein ideales Archiv zur Rekonstruktion von Hochwassern. Detritisches Material wird durch nur einen Hauptzufluss, die Ammer, in das rinnenförmige Becken transportiert. Die warvierten Sedimente erlauben eine zuverlässige Detektion und Datierung selbst mikroskopischer Hochwasserlagen. Instrumentelle Hochwasserdaten der Ammer und Wetterzeitreihen des Meteorologischen Observatoriums Hohenpeißenberg ermöglichen eine Kalibration der Sedimentdaten.

An zwei warvierten Sedimentprofilen des Ammersees (AS10<sub>prox</sub> und AS10<sub>dist</sub>), die entlang eines proximal-distalen Transekts zur Amtermündung entnommen wurden, sind hochauflösende Mikrofazies und Röntgenfluoreszenz ( $\mu$ -XRF) Analysen durchgeführt worden. Zum besseren Verständnis der Sedimentverteilung im See lag der Fokus der Untersuchungen auf der Detektion detritischer Lagen anhand ihrer sedimentologischen und geochemischen Eigenschaften und der Korrelation dieser Lagen zwischen beiden

Sedimentprofilen. Die Datierung der detritischen Lagen erfolgte durch Warvenzählung und wurde durch 14 AMS Radiokarbondatierungen an terrestrischen Pflanzenresten bestätigt.

In den Sedimenten der letzten 5500 Jahre wurden 1573 detritische Lagen in einem oder beiden der untersuchten Ammerseeprofile gefunden. Aufgrund ihrer Eigenschaften lassen sich diese Lagen als Ammerhochwasserlagen interpretieren: (1) Die Mikrofazies deutet auf eine Ablagerung nach Starkabflussereignissen hin. (2) Die geochemische Zusammensetzung beweist die terrestrische Herkunft des Materials. (3) Das proximal-distale Ablagerungsmuster deutet auf die Ammer als Eintragsquelle des Materials hin. Eine Kalibrierung mit instrumentellen Hochwasserdaten der Ammer im Zeitraum von AD 1926 bis 1999 bestätigt die Sukzession der detritischen Lagen als eine Zeitreihe starker Ammerhochwasser im Frühling und Sommer, der Hochwassersaison am Ammersee.

Die Häufigkeit der Hochwasserlagen in den letzten 5500 Jahren weist eine deutliche dekadische Variabilität auf. Trends in der Häufigkeit von Hochwasserlagen korrelieren negativ mit dem Index der East Atlantic-Western Russia Oszillation (EA-WR) während der letzten 250 Jahre (Zeitraum der durch die genutzten atmosphärischen Daten abgedeckt ist) und der solaren Aktivität während des kompletten Zeitraums. Diese Übereinstimmungen deuten möglicherweise auf einen solaren Einfluss auf die atmosphärische Zirkulation über Europa und damit auf die Häufigkeit von Hochwassern am Ammersee hin.

Weiterhin weist die Zeitreihe der Hochwasserlagen drei Veränderungen der durchschnittlichen Lagenhäufigkeit und -mächtigkeit vor etwa 5500, 2800 und 500 Jahren auf. Die Kombination der Daten beider Sedimentprofile ermöglicht es, diese Veränderungen als schrittweise Anstiege der Hochwasserintensität zu interpretieren. Vermutliche Auslöser sind graduelle Reduktion der solaren Insolation in der Nordhemisphäre und langfristige Minima der solaren Aktivität. Die wahrscheinliche atmosphärische Reaktion auf dieses Klimaforcing ist ein verstärkter Temperaturgradient zwischen den niederen und hohen Breiten, der zu einer Erhöhung der potenziellen Energie in der Atmosphäre und verstärkter Baroklinität führt. Diese Energie wird transferiert in eine Verstärkung der zyklonalen Westwindzirkulation, extremere Niederschläge und eine Intensivierung der Hochwasser am Ammersee.

Die Interpretation der Häufigkeit und Mächtigkeit von Hochwasserlagen in den Sedimenten des Ammersees ermöglicht in Kombination mit Reanalysemodellen und Zeitreihenanalysen eine Rekonstruktion der Hochwassergeschichte und die Identifizierung

hochwasserauslösender Klimafaktoren in der Ammerseeregion während der letzten 5500 Jahre. Hochwasserhäufigkeit und -intensität sind nicht stationär, sondern durch komplexe Veränderungen im Klimasystem auf Zeitskalen von Jahren bis Jahrtausenden geprägt. In diesem Zusammenhang erscheinen die Resultate globaler Klimamodelle, die einen Anstieg des Hochwasserrisikos allein auf Basis eines thermodynamisch intensivierten hydrologischen Kreislaufs infolge der Klimaerwärmung prognostizieren, als stark simplifiziert.

## **Acknowledgements**

This research was financed by a PhD grant of the Helmholtz-Centre Potsdam-GFZ German Research Centre for Geosciences.

First of all, I would like to thank my PhD supervisor Achim Brauer, head of Section 5.2 ‘Climate Dynamics and Landscape Evolution’ at the GFZ. I am grateful for his continuous support, his inspiration, and for letting me benefit from his comprehensive expertise.

I want to quote Peter Dulski, Rudolf Naumann, Gerrit Lohmann, Birgit Plessen, Norel Rimbu, and Raphael Scheffler who substantially contributed to the results of this thesis. Brian Brademann, Achim Brauer, Michael Köhler, Richard Niederreiter, Florian Ott, Oliver Rach, and Uli von Grafenstein are acknowledged for taking part in the coring campaigns at Lake Ammersee. I thank Gaby Arnold, Dieter Berger, and Michael Köhler for preparation of thin sections and am indebted to Petra Meier for C/N measurements and Helga Kemnitz for introducing me into the REM facility at the GFZ. Christine Gerschke managed the administrative work, Andreas Hendrich helped with the layout of the figures, and Marcus Günzel kept the computer running throughout the years. Thanks.

Special thank goes out to my roommates Helge Arz, Beatrice Ghilardi, Lucas Kämpf, Takeshi Nakagawa, Michael O’Connell, Florian Ott, for the right mixture of concentration, discussion, and a lots of fun. Thanks to my further PhD fellows Anoop Ambili, Ina Neugebauer, Stefan Lauterbauch, Gordon Schlolaut, Tina Swierczynski, as well as everyone at Section 5.2 of the GFZ for their astonishing engagement, continuous support, and patience.

Finally, I want to express my gratitude to all my friends and family for their love, support and inspiration.

## (1) Introduction

### 1.1. Scientific context

Climate is the principle driving force of hydrological extremes like floods, and thermodynamic increase in atmospheric water vapor is expected to increase the likelihood of such events when Earth warms (IPCC, 2007). Furthermore, natural climate variability affects the frequency and magnitude of floods on annual to millennial time-scales (IPCC, 2012). Particularly in the mid-latitudes of the Northern Hemisphere, correlations between meteorological variables and hydrological indices suggest significant effects of changing climate boundary conditions on floods (Knox, 2000; Mudelsee et al., 2003). To date, however, understanding of changes in frequency and magnitude of floods in response to varying climate forcing is limited due to the scarcity of hydrological data in space and time (IPCC, 2012). For adequately evaluating and anticipating the response of floods to changing climate boundary conditions it is, therefore, crucial to study the receptiveness of floods to natural climate forcing mechanisms on both short and long time-scales and on a regional basis (Knox, 1993; Mudelsee et al., 2003).

Geological records potentially provide long-term information on floods (Kochel and Baker, 1982). The classical approach in ‘paleoflood hydrology’ is to explore the potential of geomorphological features along the river like erosional marks, silt lines, and overbank deposits for flood reconstruction (Gilli et al., 2013). For the latter, in the backwaters of floods fine sediments deposit when the flow velocity of the transporting stream is reduced. Using multiple of these overbank deposits at different elevations in the floodplain allows to assess the magnitude of a flood. The resulting succession of flood deposits can be chronologically constrained by means of  $^{14}\text{C}$  and OSL dating (Baker, 2008). Overbank records, however, suffer from incompleteness due to erosion of earlier deposited sediments by the river and varying lateral limits of flood triggered sedimentation (Gilli et al., 2013).

Lake sediments provide more continuous records of flood activity (e.g. Noren et al., 2002; Gilli et al., 2013). During floods, detrital catchment material is transported in suspension into downstream lakes (Fig. 1.1) and deposited as a distinct detrital layer, when the transport capacity of the inflowing turbidity current successively diminishes in the water body

(Lambert et al., 1976; Sturm and Matter, 1978). Even though already recognized in the late 1970's the potential of flood triggered detrital layers in lakes for long flood calendars was not explored until more than a decade later, when Siegenthaler and Sturm (1991) established a 700-year record of extreme floods from sediments of Lake Uri. Since then, a growing number of flood reconstructions particularly from Europe and North America has been established using various geochemical, geophysical, and biological proxies on non-varved lake sediments (e.g. Thorndycraft et al., 1998; Nesje et al., 2001; Noren et al., 2002; Chapron et al., 2002; Gilli et al., 2003; Arnaud et al., 2005; Osleger et al., 2009; Støren et al., 2010; Debret et al., 2010; Stewart et al., 2011; Gilli et al., 2012; Wilhelm et al., 2012). These flood records provide valuable data on multi-decadal changes in flood frequency and magnitude in response to varying natural baseline climate, but lack the time-resolution necessary for identifying short-term flood variability and seasonality.

**Figure 1.1.** Suspended sediments in Lake Ammersee supplied by Ammer river floods.

Intra-annual climate variability, however, strongly affects regional flood characteristics with respect to triggering atmospheric circulation patterns (Mudelsee et al., 2003; Sivapalan et al., 2005). Varved lake sediments allow to isolate these effects. Individual flood layers can be dated to the season by varve counting and determination of the microstratigraphic position within an annual sedimentation cycle (Fig. 1.2) (Mangili et al., 2005; Czymzik et al., 2010; Swierczynski et al., 2012a). In addition, the seasonal resolution narrows the usually decadal to multi-decadal gap between geological and instrumental data and enables a more direct calibration of flood layer time-series with measured runoff records (Czymzik et al., 2010).

**Figure 1.2.** Determination of flood layer seasonality in Lake Ammersee sediments by the microstratigraphic position within a varve.

## 1.2. Site and sediments

*Lake Ammersee* is located in the pre-alpine region of southern Germany ~20 km southwest of Munich (48°00'N, 11°07'E), at an elevation of 533 m asl. (Fig. 1.3) The basin was eroded into Cenozoic sediments by the Ammersee lobe of the Isar-Loisach glacier. The present day lake has a surface area of 47 km<sup>2</sup> and a maximum water depth of 81 m (Alefs, 1997).

Previous studies on oxygen isotopes from ostracods have proven the sediment record as a reliable paleoclimate archive enabling high-resolution temperature reconstruction (von Grafenstein et al., 1996; 1999). Annual layering of the sediments enables precise detection and dating of flood triggered fluxes of catchment material into the lake (Alefs, 1997). Flysch, molasse, and late moraine formations in the meso-scale catchment provide abundant fine-grained detrital material for downstream transport into the gully shaped lake by only one main tributary, River Ammer (Fig. 1.3). High water tables in the northern part of the catchment and low water holding capacities of the alpine soils favor the translation of extreme rainfall into floods through saturation excess overland flow (Ludwig et al., 2003). Available instrumental River Ammer runoff data back to AD 1926 (provided by the Wasserwirtschaftsamt Weilheim) allow calibrating the sedimentary record.

Today, hydrology in the Ammersee region is controlled by competing influences of maritime cyclonic weather regimes transporting moisture from the North Atlantic into central Europe and continental atmospheric blocking by high-pressure cells (Petrow and Merz, 2009). Mean annual precipitation is 1200 mm. The strongest River Ammer floods occur after rainfall maxima from late spring to summer (Czymzik et al., 2010).

**Figure 1.3.** Geographical position and bathymetric map of Lake Ammersee showing the Ammer river inflow and coring locations of sediment profiles AS10<sub>prox</sub> and AS10<sub>dist</sub>.

*Continuous sediment profiles AS10<sub>prox</sub> and AS10<sub>dist</sub>.* In summer 2010, at two locations in the profundal of Lake Ammersee, overlapping sediment cores consisting of 2 m segments were retrieved at a distance of a few meters using a modified UWITEC piston corer installed on a stationary float (Fig. 1.4). Sediment profile AS10<sub>prox</sub> (overlapping cores C and D) is located in a more proximal (4.4 km) and sediment profile AS10<sub>dist</sub> (overlapping cores A and B) in a more distal (6.2 km) position towards the Ammer river inlet. Retrieving parallel sediment cores with overlapping segments enables to establish continuous composite profiles. Short sediment cores AS07-P1 and AS07-P2 (Manuscript 1) were retrieved from the same locations as sediment profiles AS10<sub>dist</sub> and AS10<sub>prox</sub> (Manuscripts 2 and 3) and, thus, represent parallel sequences.

**Figure 1.4.** Sediment coring on Lake Ammersee in summer 2010 using a modified UWITEC piston corer installed on a stationary float.

### 1.3. Scientific objectives

(1) Primary scientific objective of this thesis is *to explore and better understand the potential of varved lake sediments as long-term seasonally resolved flood archives*. Flood layer deposition is influenced by both climatic impacts and environmental effects like e.g. anthropogenic land-use change and seasonally varying soil moisture and erosion conditions. A systematic survey of the results from both Lake Ammersee sediment profiles will shed light on the physical processes behind detrital layer deposition and allow to better distinguish both effects.

(2) The varved nature of Lake Ammersee sediments reduces the usually decadal-scale resolution of non-varved lake sediment records to the season allowing to better calibrate the sediment data using instrumental time-series. *Comparison to instrumental River Ammer runoff and meteorological data from the Meteorological Observatory Hohenpeißenberg* will help to assess the 'completeness' of the geological flood record and enables a process-orientated evaluation of detrital deposition, based on a broad database for each single event.

(3) Further scientific objective is *to attribute flood generating climate forcing mechanisms* by comparison with well-dated paleoclimate and climate forcing time-series and using reanalysis

models. The selected time interval covering the last 5500 years is suitable to adequately detect flood-triggering climate mechanisms on both short and long time-scales.

#### 1.4. Scientific tasks/Methods

Establishment of a seasonal flood layer record from two varved sediment profiles includes three main methodological steps:

(1) *Microscopic microfacies analyses on overlapping petrographic thin sections and X-ray fluorescence scanning at 200  $\mu\text{m}$  step size* on Lake Ammersee sediment profiles AS10<sub>prox</sub> and AS10<sub>dist</sub> to detect the sedimentological and geochemical features of even fractions of a mm thick detrital layers (Fig. 1.5).

(2) *Microscopic varve counting*, verified by accelerator mass spectrometry (AMS)  $^{14}\text{C}$  dating of terrestrial plant macrofossils, for down to seasonally resolved flood layer stratigraphies.

(3) *Intra-basin correlation of flood layers in AS10<sub>prox</sub> and AS10<sub>dist</sub>* by means of varve chronology and stratigraphy in order to better understand sediment transport and deposition processes within the lake basin.

To investigate Lake Ammersee sediments in more detail, the continuous high-resolution record is complemented by multi-proxy analyses of discrete varve and detrital layer samples. The methodological approach includes X-ray diffractometry, scanning electron microscopy, grain-size analyses with a laser particle sizer, stable oxygen and carbon isotope ratios, as well as total carbon and nitrogen contents.

**Figure 1.5.** Thin section scan showing Lake Ammersee varves and detrital layers overlain by corresponding  $\mu$ -XRF data of the elements Titan (Ti) and Calcium (Ca).

## 1.5. Organization of the thesis

The thesis is conceptualized as a ‘cumulative thesis’ subdivided into seven chapters and a data appendix. Following this introduction giving essential background information (Chapter 1), chapters 2 to 4 present the scientific work subdivided into three manuscripts (Table 1.1). The essentials of the three manuscripts build up on each other. The first manuscript titled ‘A 450-year record of spring-summer flood layers in annually laminated sediments from Lake Ammersee (southern Germany)’ (Chapter 2) informs about the establishment of a 450-year flood layer time-series from two varved short sediment cores of Lake Ammersee. In order to verify the detrital layer succession as a flood record through time and to better understand flood triggering atmospheric circulation at Lake Ammersee, the time-series is calibrated with instrumental runoff, local precipitation, and weather regime data. The second manuscript ‘Shifts of Mid- to Late Holocene flood intensity in detrital layers from varved sediments of pre-alpine Lake Ammersee (southern Germany)’ (Chapter 3) informs about the reconstruction of a 5500-year flood layer time-series from two varved Lake Ammersee sediment profiles and gives detailed insight into sedimentology and geochemistry of the cores, chronological issues, and correlation of both sediment profiles. The interpretation section of the manuscript elaborates on potential biases in flood layer time-series, as well as multi-millennial effects on flood intensity at Lake Ammersee. The third manuscript ‘Atmospheric control of flood frequency in central Europe throughout the past 5500 years’ (Chapter 4) focuses on paleoclimatological issues. Decadal to millennial-scale correlations of flood frequency at Lake Ammersee with climate variables are presented and potential flood triggering atmospheric mechanisms are analyzed by means of reanalysis models. Summary and conclusions of the thesis are given in chapter 5. The references are listed in chapter 6. Flood layer data from AS10<sub>prox</sub> and AS10<sub>dist</sub> are presented in the data appendix (Chapter 7) and are/will be available at the PANGAEA data library after publication of the single manuscripts.

## 1.6. Author's contribution

*Manuscript 1 (Chapter 2).* I performed microfacies analyses and varve counting on two short sediment cores, measured  $\mu$ -XRF data in cooperation with Peter Dulski, oxygen and carbon isotope ratios, as well as total carbon and nitrogen contents in cooperation with Birgit Plessen, XRD data in cooperation with Rudolf Naumann, and took scanning electron microscopy photos in cooperation with Helga Kemnitz. I analyzed the data, reviewed the relevant literature, and wrote the manuscript. I developed the idea of a flood record and calibrated the detrital layer stratigraphy with instrumental River Ammer runoff and weather regime data. The co-authors, the reviewers, and particularly Achim Brauer substantially helped to improve the final manuscript.

*Manuscript 2 (Chapter 3).* I organized and lead the coring campaign at Lake Ammersee. I constructed the composite profiles, performed microfacies analyses, varve counting, and intra-basin correlation. I performed  $\mu$ -XRF measurements in collaboration with Peter Dulski, total carbon and nitrogen measurements in collaboration with Birgit Plessen, XRD measurements in collaboration with Rudolf Naumann, and laser particle sizer grain-size measurements. I analyzed all data, reviewed the relevant literature, and wrote the manuscript. I induced the concept of combined orbital and solar forcing on flood intensity at Lake Ammersee. Achim

Brauer critically reviewed and substantially improved the draft manuscript. The co-authors reviewed the paper.

*Manuscript 3 (Chapter 4).* I analyzed microfacies and  $\mu$ -XRF data, developed the idea of a solar influence on atmospheric circulation and flood frequency at Lake Ammersee, and wrote the draft manuscript. Gerrit Lohmann and Norel Rimbu established reanalysis models and performed single spectrum analyses. All co-authors critically reviewed and helped to improve the manuscript.

**Abstract.** A 450-year spring-summer flood layer time-series at seasonal resolution has been established from the varved sediment record of Lake Ammersee (southern Germany) applying a novel methodological approach. The main results are (1) a precise chronology obtained by microscopic varve counting, (2) the identification of detrital layers representing flood-triggered fluxes of catchment material into the lake, and (3) the recognition of the seasonality of these flood layers from their micro-stratigraphic position within a varve. Tracing flood layers in a proximal and a distal core and correlating them applying the precise chronology provided information on the depositional processes. Comparing the seasonal flood layer record with daily runoff data of the inflowing River Ammer for the period from 1926 to 1999 allowed defining an approximate threshold in flood magnitude above which the formation of flood layers becomes very likely. Moreover, it was for the first time possible to estimate the 'completeness' of the flood layer time-series and to recognize that mainly floods in spring and summer representing the main flood seasons in this region are well preserved in the sediment archive. Their frequency distribution over the entire 450-year time-series is not stationary, but reveals maxima for colder periods of the Little Ice Age when solar activity was reduced. The observed spring-summer flood layer frequency further shows similar trends as the occurrence of flood-prone weather regimes since AD 1881, probably suggesting a causal link between solar variability and changes in mid-latitude atmospheric circulation patterns.

## 2.1. Introduction

Assumptions about an increase in extreme flood events due to an intensified hydrological cycle caused by global warming still are in discussion and have to be better verified. Statistical flood analyses indicate that simple mechanistic explanations are not straightforward and that complex seasonal (Mudelsee et al., 2003) and regional (Petrow and Merz, 2009) effects have to be considered. Some historical flood records even indicate that flood frequencies were higher during colder periods (Knox, 1993; Glaser and Stangl, 2004) questioning the hypothesis of a correlation between the frequency of extreme floods and warmer climate. However, the length of presently available flood time-series is not sufficient for a profound understanding of possible relations between flood frequencies and climatic boundary conditions. This is largely due to the lack of long-term instrumental flood data that rarely exceeds a century (Baker, 2006) and thus only covers the period of strongest human interferences in most river catchments.

In addition to the extension of flood time-series into the recent past by exploiting historical archives, natural archives are available that record climate changes and the occurrence of extreme events even much further back in times without any human activity. Particularly, river and lake sediments have been proven as suitable long flood records (e.g. Dearing, 1991; Thorndycraft et al., 1998; Dearing et al., 2001; Thorndycraft and Benito, 2006). These geological archives provide crucial information for a better evaluation of flood occurrences under different climate boundary conditions, which are often not considered for flood frequency calculations assuming a stationary climate (Knox and Kundzewicz, 1997). However, it must be considered that investigating geological archives focusing on extreme event occurrences is still at its beginning. One key question is the degree of ‘completeness’ to which geological archives record flood events. Filling this gap in knowledge requires calibrating the paleoflood record with instrumental and/or historical flood data. However, merging geological and instrumental time-series is not straightforward because of their very different temporal resolution. A novel approach to bridge these gaps in time resolution is to reduce the commonly not better than decadal-scale resolution of geo-archives by utilizing annually laminated lake sediments. Fine, millimeter to sub-millimeter laminations in lake sediments formed by seasonally varying deposition processes are defined as varves and provide both, precise time control by varve counting and climatic and environmental information at seasonal resolution (Brauer and Casanova, 2001; Brauer, 2004).

In varved lake sediments, flood-triggered fluxes of eroded fine catchment material result in the deposition of characteristic detrital layers which can be determined with seasonal precision by their micro-stratigraphical position within the annual sedimentation cycle (Mangili et al., 2005; Brauer et al., 2008). However, reconstructing flood time-series from lake sediments necessitates a comprehensive understanding of the entire cascade of processes from sediment erosion and transport in the catchment, to distribution and deposition in the lake basin in order to rule out other causes for event layer deposition such as slope failure or debris flow (Mangili et al., 2005; Swierczynski et al., 2009).

Lake Ammersee is an ideal location to build up a long flood record because previous work has proven this sediment profile a sensitive proxy archive for high-resolution paleotemperature reconstruction (e.g., von Grafenstein et al., 1996, 1999). Preservation of annual laminations enables accurate detection and precise dating of flood triggered detrital material in the sediment with seasonal precision. In addition, a wealth of meteorological and hydrological data is available from local authorities in order to compare the geological and instrumental time-series. Therefore, two new short sediment cores have been studied applying a novel methodological approach which combines microfacies analyses, high-resolution element scanning ( $\mu$ -XRF), stable isotope data from bulk carbonate samples ( $\delta^{13}\text{C}_{\text{carb}}$ ,  $\delta^{18}\text{O}_{\text{carb}}$ ), and X-ray diffraction (XRD) analyses (Brauer et al., 2009). Integrating these analytical techniques enables a better and more precise identification and interpretation of flood layers at microscopic scales which previously have not been detected.

## 2.2. Study Site

Lake Ammersee (533 m asl.) is a hardwater lake located in South Germany (48°00'N, 11°07'E) with a surface area of 47 km<sup>2</sup> and a maximum depth of 81.1 m (Fig. 2.1). The 16.2 km long and 2.8 km wide basin is shaped into Cenozoic sediments by the Ammersee lobe of the Isar-Loisach glacier (Alefs, 1997). The catchment of the main tributary River Ammer has a size of 709 km<sup>2</sup> and reaches a maximum elevation of 2185 m asl. (Ludwig et al, 2003). The Ammer arises in the Bavarian Calcareous Alps and flows northwards through smoothly shaped pre-alpine flysch, molasse, and late moraine formations (Mangelsdorf and Zelinka, 1973) before entering the lake at its southern end (Fig. 2.1). Detrital sediment is supplied to the lake nearly exclusively by the Ammer River (Alefs, 1997). Secondary inflows like the River Rott and the Fischbach have negligible effects on the detrital sediment supply into the

lake basin (LFW, 2005). The Ammer river mouth was artificially displaced for approx. 1 km to the southeastern part of the lake during channelization of the river bed between AD 1920 and 1924 (Alefs, 1997) (hereafter all dates are given in the AD notation). Before that time the River Ammer inlet was located at the present-day inlet of the River Rott, a former Ammer tributary (Fig. 2.1).

The Ammer catchment is located in the hydrologic transition zone between maritime North-Atlantic and continental climate influenced by both, weather regimes related to frequent cyclonic westerly airflow and atmospheric blocking through high-pressure fields (Petrow and Merz, 2009). The pluvio-nival runoff regime indicates maximum flow rates during the transition from snow melt periods in spring to precipitation maxima in summer. Limited storage capacities of the alpine soils and high water tables in the northern valleys of the catchment favor frequent floods dominated by saturation excess overland flow. The steep (relief difference of 1652 m) and rather small catchment favors short but high runoff peaks (Ludwig et al, 2003).

**Figure 2.1.** (a) Geographical overview and (b) bathymetric map of Lake Ammersee including positions of cores AS07-P1 (distal) and AS07-P2 (proximal). (c) Hydrogeological sketch of the Ammer catchment.

## 2.3. Methods

### 2.3.1. Sediment coring

Two short sediment cores (AS07-P1= 133 cm and AS07-P2 = 134 cm) were retrieved from the deepest part of the lake basin in June 2007 with a modified UWITEC short-core system. Core AS07-P1 is located in a distal (6.2 km) and core AS07-P2 in a more proximal (4.4 km) position towards the Ammer river mouth (Fig. 2.1).

### 2.3.2. Microfacies analyses

For microfacies analyses and measurements of seasonal sub-layer properties, two overlapping series of 16 thin sections from core AS07-P1 and 9 thin sections from core AS07-P2 were investigated using a petrographic microscope (Carl Zeiss-Axiophot, Jena). Preparation of undisturbed thin sections from wet and soft sediments is a crucial methodological prerequisite to adequately perform micro-stratigraphical investigations and includes careful freeze-drying and epoxy resin impregnation (Brauer and Casanova, 2001). The bottom part of core AS07-P2 was disturbed during core-splitting thus preventing from further thin section preparation. Consequently, the investigated interval of this core is shorter. Various magnifications, optical and light conditions were used for microfacies analyses. Thickness measurements of detrital layers were performed at 25x magnification. Microfacies analyses were not always applicable for very thin detrital layers (< 1 mm). A precise chronology was constructed by calcite varve counting. Short intervals of poor varve preservation were interpolated using annual sedimentation rates as calculated from varve thickness measurements in well-preserved adjacent varve sections.

Owing to the disturbances in the bottom part of core AS07-P2 and higher sedimentation rates at this more proximal location, this core covers a shorter time interval than the distal core AS07-P1. Therefore, precise varve-to-varve correlation including comparison of microfacies is available only for the upper 60 cm of the distal core AS07-P1 covering the last 200 years (Fig. 2.2). The older interval of the entire 450-year flood layer record has been established from the bottom part of core AS07-P1 alone without the parallel sediment sequence from the proximal site.

**Figure 2.2.** (left) Varve-to-varve correlation of detrital layers D1 to D34 and monospecific diatom layers DIA1 to DIA3 (white bars; not mentioned in the text) between core AS07-P1 and AS07-P2. Dark gray bars mark microscopically correlated detrital layers showing both, the same micro-stratigraphic position and microfacies. Correlating detrital layers indicated with light gray bars exhibit different microfacies in each core. (right) Thin section scan with polarizing filter but without microscopic magnification showing calcite varves with intercalated detrital and diatom layers (AS07-P1, 3-8 cm core depth). Distinct positive  $\mu$ -XRF excursions of the element Ti (cps) indicate detrital layers. Calcite layers are represented by positive Ca (cps) and darker layers by small positive Ti (cps) excursions.

### 2.3.3. Micro X-ray fluorescence scanning, stable isotope ratios from bulk carbonates, and X-ray diffraction

Microscopic data have been combined with high-resolution element scanning ( $\mu$ -XRF), stable isotope ratios from bulk carbonate samples ( $\delta^{18}\text{O}_{\text{carb}}$ ,  $\delta^{13}\text{C}_{\text{carb}}$ ), and X-ray diffraction (XRD). Micro-XRF scanning of major elements (Mg, Al, Si, P, S, Cl, K, Ca, Ti, Mn, Fe, Sr) at 200  $\mu\text{m}$  resolution has been carried out on the fresh sediment surface of both cores with an EAGLE III BKA  $\mu$ -XRF spectrometer (Röntgenanalytik Messtechnik GmbH, Taunusstein). The resulting time resolution is about 10 data points for each varve (*i.e.* year). The scanner data can be precisely matched to microfacies data because both datasets were measured from the same section plane of the splitted cores (Brauer et al., 2009). For single line measurements

the tube voltage was set at 40 kV, with a tube current of 450  $\mu$ A. Dwell time for each measurement was 30 seconds. Each data point reflects the mean element intensity of one measured spot, expressed in counts per second (cps).

Stable oxygen and carbon isotope ratios of bulk carbonate samples were measured with a GasBench II (Thermo Electron, Bremen) connected to a DELTAplusXL Isotope Ratio Mass Spectrometer (ThermoFisher Scientific, Waltham) working in continuous flow mode. Samples were extracted from freeze dried and powdered 5 mm sediment slices of both cores representing a two-year resolution. Depending on the carbonate content, 0.25 to 0.5 mg of sample material was loaded into 10 ml vials. After automatically flushing the vials with He, the samples were treated with 100 % phosphoric acid at 75°C for 60 min in the GasBench preparation system following the analytical procedure described in Spötl and Vennemann (2003). Isotopic compositions of the samples are given relative to the VPDB standard in the  $\delta$  notation.  $\delta_A = (R_{SA}/R_{ST} - 1) \times 10^3$  (‰), where  $R_{SA}$  is the isotopic ratio ( $^{13}\text{C}/^{12}\text{C}$ ;  $^{18}\text{O}/^{16}\text{O}$ ) of the sample and  $R_{ST}$  that of the standard. Calibration was performed against three international reference standards (NBS 19, CO1, CO8). The 1-sigma precision of replicate measurements of NSB 19 is 0.06‰ for  $\delta^{13}\text{C}$  and 0.08‰ for  $\delta^{18}\text{O}$ .

XRD analyses of 11 representative samples selected by microscopic observations were carried out using a Siemens Diffraktometer 5000 (Siemens, Karlsruhe). Seven measurements were performed on 1 cm sediment samples reflecting the different types of detrital microfacies. Four measurements were carried out on 1 cm bulk samples of regularly varved sediment, thus representing 4-5 varve years.

## 2.4. Results

### 2.4.1. Varve microfacies and chronology

The sediments consist of calcite varves with intercalated detrital layers (Alefs, 1997; Alefs and Müller, 1999). 97 % of the sediment profile exhibits well known structures of calcite varves consisting of couplets of discrete light calcite layers and darker organic layers (e.g. Lotter and Lemcke, 1999; Brauer et al., 2008). Since endogenic calcite precipitation is mainly induced through (1) biogenic assimilation of  $\text{CO}_2$  by photosynthesizing phytoplankton and (2) temperature increase (Kelts and Hsü, 1978; Stabel, 1986; Bluszcz et al., 2008) calcite layers form in the spring-summer season. Darker layers consist of detrital and amorphous organic

material, and littoral calcite, all internally re-deposited through wave activity during fall and winter seasons. A clear change in varve microfacies is observed for the interval from 1960 to 1980. During this period, two sub-layers of a coarser (5-7  $\mu\text{m}$ ) basal and a finer (2-4  $\mu\text{m}$ ) upper calcite layer were deposited, each preceded by a diatom layer. This double calcite layer pattern is related to higher productivity during the lake's main eutrophication phase and has been also observed at Lake Zurich (Kelts and Hsü, 1978).

**Figure 2.3.** Comparison of varve chronologies for AS07-P1 and AS07-P2. Varves counted between two marker layers and corrections made for the composite chronology.

In the first step, two independent varve chronologies were established for each core by microscopic calcite varve counting from 1999 back to 1545 (AS07-P1) and 1800 (AS07-P2). The disturbed sediment-water interface due to the coring process prevented from counting the uppermost seven varves. Therefore, the resulting chronology was floating and had to be anchored to the absolute time scale using an exceptional detrital layer of known age (D2, Fig. 2.2). Sediment trap studies close to the coring site of AS07-P2 have proven the deposition of this layer in July 1993 (Alefs et al., 1996) after a break-up of an armor layer in the Ammer tributary Halbammer (see section 2.5.1). The deposition time of this layer is confirmed by a sediment core obtained from Lake Ammersee on October 06<sup>th</sup> 1993 (AS T<sub>max</sub>93) by U. von Grafenstein showing layer D2 on the top of the core. Some short intervals of poor varve

preservation comprising between two and six years appear in 14.9 % of AS07-P1 and in 22.5 % of AS07-P2. These intervals were interpolated using the mean varve thickness of well-preserved adjacent sediment intervals (2.2 mm for AS07-P1 and 2.6 mm for AS07-P2).

In the second step, a composite chronology was established back to 1800 through combining counts of the best preserved parts of each chronology ('best-of' composite). This has been achieved through comparison of varve counts separately for 26 intervals of about the same length precisely defined through distinct marker layers (Fig. 2.3). Such detailed comparison allowed identification of even single missing varves in either of the cores and to bridge poorly preserved varve intervals in one core by using the varve count from the parallel core (Brauer et al., 2008).

In the final step, the resulting composite chronology was compared with historical Ammer flood observations from the city chronicle of Weilheim/Ammer (Alefs, 1997) indicating an over-estimation of two varves in the interval from 1884 to 1912. The entire varve chronology back to 1545 has then been corrected for this bias. The resulting composite chronology differs less than 2% from a previous varve chronology for Lake Ammersee sediments reaching back to 1786 (Alefs, 1997).

#### 2.4.2. Detrital layer microfacies

Three main classes of detrital microfacies have been distinguished in the studied sediment interval: (1) graded layers, (2) silt/clay layers, and (3) matrix-supported layers (Fig. 2.4). Thirty-four detrital layers in the parallel parts of both cores were studied and compared in detail for microfacies and layer thickness:

1. *Graded layers.* This layer type is characterized by a normal grading from fine sand and coarse silt (average grain size of 30  $\mu\text{m}$ ) to clay ( $< 2 \mu\text{m}$ ). A sharp lower boundary clearly segregates the basal part of the layer from the underlying sediment. Multiple grading and flame structures in the basal part appear within few layers of this type. Thirteen of 34 correlating detrital layers exhibit this microfacies in both cores. The thickest graded layer is 10.8 mm (Figs. 2.4 and 2.5).

2. *Silt/clay layers.* No particular textural organization, except for a hardly visible faint grading in few cases, defines this layer type. The fine silt/clay detritus lacks the coarser material included in graded layers but shows the same elemental, isotopic, and mineralogical

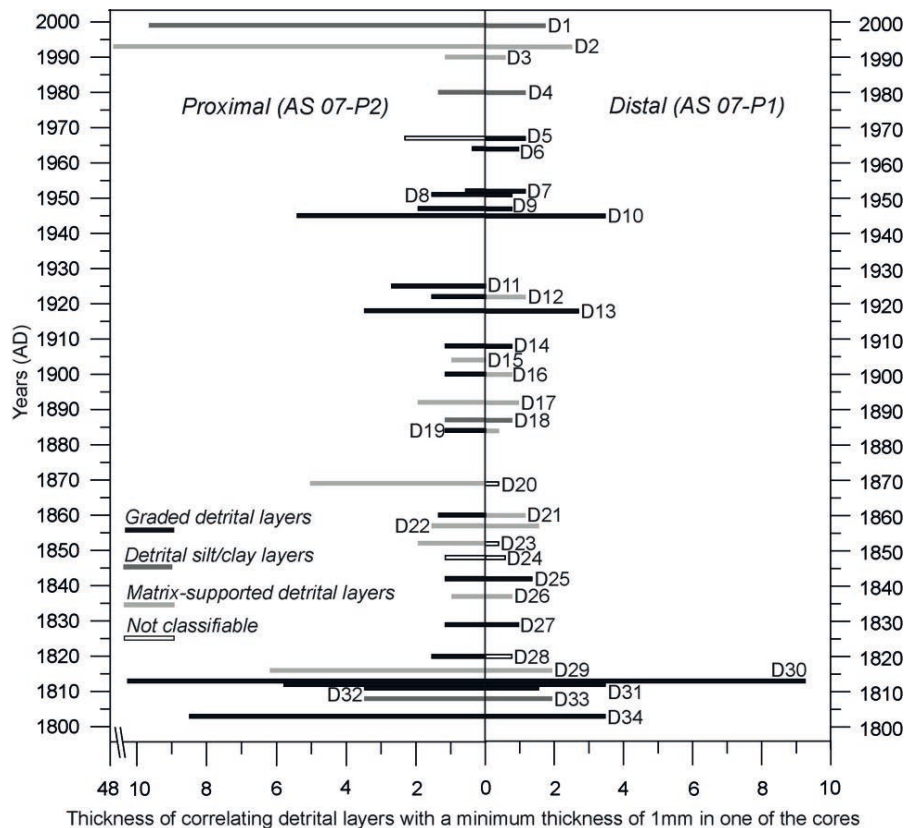

composition as the other detrital microfacies (see section 2.4.3). Four of 34 correlating detrital layers exhibit this layer type in both cores (Figs. 2.4 and 2.5). The thickest layer of this type is 9.6 mm.

3. *Matrix-supported layers.* These layers consist of predominantly fine sand to coarse silt detrital grains in a matrix of clots of endogenic calcite. Horizontally oriented plant remains and littoral diatoms appear solely in this layer type. The textural organization shows in a few cases weak grading. Six of 34 correlating detrital layers are matrix-supported layers in both cores (Figs. 2.4 and 2.5). The thickest matrix-supported layer is 47.1 mm (D2).

**Figure 2.4.** Polarized microscope photos (25x) and thin section scans of detrital microfacies: (1) graded layers, (2) silt/clay layers, and (3) matrix-supported layers. Detrital microfacies are confirmed by positive Ti and negative Ca  $\mu$ -XRF excursions. Note that microscope and thin section images are from different layers.

Varve-to-varve correlation between both cores allowed identifying differences in microfacies for the same event of detrital matter flux into the lake basin and provides information on sediment transport processes within the lake. Four out of 34 layers exhibit different microfacies in each core. These are graded layers in the proximal core AS07-P2 which correlate to matrix-supported layers in the distal core AS07-P1 (D12, D16, D19, D21). For one graded (D11) and one matrix-supported layer (D15) in the proximal core, no correlating layer has been found in the distal core (Fig. 2.5). In one case (D 11) this might be due to slight sediment distortions probably caused during sample preparation, while the amount of detrital matter forming layer D15 at the proximal site was too low (very thin layer) to reach the distal core position. Microfacies types for four layers could not be unambiguously classified in one of the cores (Fig. 2.5): two of these are matrix-supported layers in the proximal core (D20, D23), one is a graded layer in the proximal core (D28), and one a graded layer in the distal core (D5). One layer was not classifiable in both cores (D24). A likely explanation for these problems in microfacies classification are minor artifacts caused during sample preparation.

**Figure 2.5.** Thickness and microfacies for detrital layers thicker than 1 mm in one of the cores (AS07-P1 and AS07-P2) between 1800 and 1999 (time span covered by both cores).

Detrital layer thickness of all three detrital microfacies exhibits a distinct proximal-distal pattern (Figs. 2.2 and 2.5). Consequently, the accumulated detrital layer thickness is by a factor of 2.6 higher in the proximal core. Thirty of 34 detrital layers are as expected thicker in the proximal core AS07-P2. The four exceptions either are equally thick (D22) or slightly thicker (D6, D7, D25) in the distal core (Fig. 2.5). However, these differences in thickness measurements are not significant and likely biased by sediment disturbances during sample preparation.

#### 2.4.3. Composition of detrital layers

$\mu$ -XRF scanning provides high-resolution data of major element variations. Ti was selected as indicator for detrital input since it is redox-insensitive and clearly of terrigenous origin (Binder, 1999; Haug et al., 2001). Positive correlations in cores AS07-P1 and AS07-P2 between Ti and Fe ( $r = 0.87/0.90$ ), K ( $r = 0.88/0.89$ ), Si ( $r = 0.74/0.77$ ), and Al ( $r = 0.55/0.60$ ) indicate this element cluster as of detrital origin. Ca in contrast, is strongly anticorrelated to Ti and exhibits a stronger anticorrelation in the proximal core AS07-P2 ( $r = -0.53/-0.70$ ). Confirming microfacies analyses,  $\mu$ -XRF profiles exhibit distinct positive Ti and negative Ca excursions for detrital layers (Figs. 2.2, 2.4, and 2.6). Mg count rates are very low and thus do not exhibit variations for a reliable interpretation. XRD analyses reveal quartz, calcite, albite, and clinocllore as mineral phases in all detrital microfacies. A very weak signal of dolomite is in agreement with the low  $\mu$ -XRF Mg count rates. This result differs from reports by Müller and Sigl (1977) who describe dolomite as a main mineral phase in the surface sediments near the Ammer river mouth.

$\delta^{18}\text{O}_{\text{carb}}$  isotope values from core AS07-P1 range between  $-9.62\text{‰}$  and  $-5.71\text{‰}$  with an average of  $-7.67\text{‰}$ , while  $\delta^{18}\text{O}_{\text{carb}}$  isotope values from core AS07-P2 range between  $-9.30\text{‰}$  and  $-3.96\text{‰}$  with an average of  $-7.03\text{‰}$ .  $\delta^{13}\text{C}_{\text{carb}}$  isotope values from core AS07-P1 range between  $-5.69\text{‰}$  and  $-1.70\text{‰}$  with an average of  $-4.15\text{‰}$ , while  $\delta^{13}\text{C}_{\text{carb}}$  isotope values from core AS07-P2 range between  $-5.31\text{‰}$  and  $0.22\text{‰}$  with an average of  $-3.44\text{‰}$  (Fig. 2.6). For both cores, a strong covariance between  $\delta^{18}\text{O}_{\text{carb}}$  and  $\delta^{13}\text{C}_{\text{carb}}$  is revealed (AS07-P1,  $r = 0.91$ ; AS07-P2,  $r = 0.98$ ). Covariance of  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  commonly indicates either a hydrologically closed lake system (Leng and Marshall, 2004) or detrital contamination (Mangili et al., 2010).

**Figure 2.6.** (a)  $\delta^{18}\text{O}_{\text{ostracods}}$  (von Grafenstein et al., 1992), Ti count rates (cps),  $\delta^{13}\text{C}_{\text{carb}}$  and  $\delta^{18}\text{O}_{\text{carb}}$  (‰) data from core AS07-P1. (b) The highlighted varve interval underlain by a core photo exhibits detrital layers (white bars) with coinciding positive Ti (cps) excursions, heavier  $\delta^{13}\text{C}_{\text{carb}}$  and  $\delta^{18}\text{O}_{\text{carb}}$  values. Note the different resolution of  $\mu\text{-XRF}$  (200  $\mu\text{m}$ ) and stable isotope data (0.5 cm).

Since Lake Ammersee is a hydrologically open lake system (Alefs, 1997) and clearly heavier isotope peaks coincide with detrital microfacies, it is obvious that  $\delta^{18}\text{O}_{\text{carb}}$  and  $\delta^{13}\text{C}_{\text{carb}}$  data are mainly controlled by detrital (carbonate) contamination and do not reflect climatic fluctuations as  $\delta^{18}\text{O}$  from benthic ostracods in Lake Ammersee (von Grafenstein et al., 1992, 1996, 1999) (Fig. 2.6). This result is confirmed by isotope measurements of six samples of fine grained detrital Ammer riverbed material from three locations (Fig. 2.1) indicating heavy isotope values between  $-4.54\text{‰}$  and  $-3.29\text{‰}$  with a mean of  $-3.58\text{‰}$  for  $\delta^{18}\text{O}_{\text{carb}}$ , and  $1.04\text{‰}$  and  $1.70\text{‰}$  with a mean of  $1.37\text{‰}$  for  $\delta^{13}\text{C}_{\text{carb}}$  (Fig. 2.6). A wider isotope value range, heavier average and maximum isotope values suggest a higher detrital contamination in the proximal core AS07-P2. Source of the detrital carbonates are probably outcrops of Cretaceous and Triassic carbonates, late moraine, flysch, and molasse formations in the Ammer catchment, all containing considerable amounts of calcite. The period of strongest eutrophication between 1960 and 1980 (Alefs, 1997; Alefs and Müller, 1999) is reflected by more negative  $\delta^{18}\text{O}_{\text{carb}}$  values in the Lake Ammersee sediments (Fig. 2.6).

**Table 2.1.** Runoff and precipitation data for the 17 highest River Ammer floods (daily runoff  $\geq 125$  m<sup>3</sup>/s), date of deposition, and thickness of detrital layers from 1926 to 1999 and for floods below 125 m<sup>3</sup>/s causing detrital layer deposition<sup>a</sup>.

<sup>a</sup>Categories for flood events are:  $\geq 150$  m<sup>3</sup>/s=3,  $\geq 125$  m<sup>3</sup>/s=2,  $\geq 100$  m<sup>3</sup>/s=1, and  $< 100$  m<sup>3</sup>/s=0. Detrital layer thickness is from core AS07-P1 except when marked with \* (than AS07-P2). Precipitation sums for flood events are calculated by adding the daily precipitation during and two days before  $\geq 100$  m<sup>3</sup>/s daily runoff.

#### 2.4.4. Seasonal detrital layers versus instrumental data (1926-1999)

A comparison of the detrital layer record from of the composite profile with instrumental daily runoff data from 1926 to 1999 proves that all detrital layers deposited during this time interval have been triggered by floods (Table 2.1) and confirms the micro-stratigraphically determined seasonality of flood layers. For 15 of 22 detrital layers the ascertained season has been exactly determined. Three detrital layers designated as ‘summer’ layers correspond to May floods, two designated ‘spring’ layers correspond to February floods, while two other designated ‘spring’ layers reflect a June flood (Table 2.1). These uncertainties are due to the criteria used for determining the season of a detrital layer. A ‘summer’ layer is defined as a

layer deposited after initial calcite formation in the lake. Since calcite formation in warm years may start as early as March or April, a detrital layer triggered by a May flood may appear as ‘summer’ layer in the micro-stratigraphic record. Flood layers deposited directly before the onset of calcite precipitation are considered as ‘spring’ layers, so that a February flood layer may appear as ‘spring’ layer. Interpretation of June floods as ‘spring’ layers can be explained by micro-erosion that could have displaced the thin layer of precipitated calcite on the lake floor. Taken these information into consideration makes us confident to have obtained a reasonably precise seasonal flood layer record.

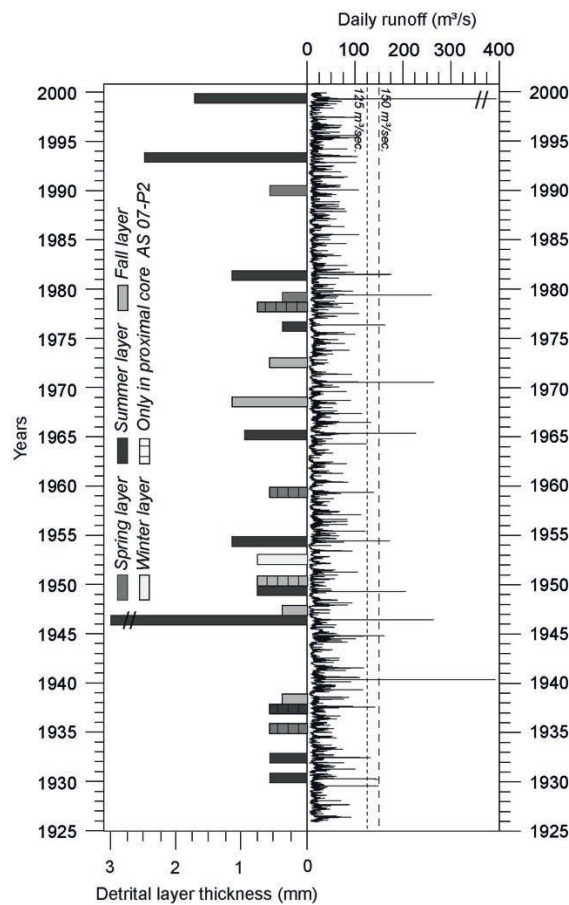

**Figure 2.7.** Seasonal distribution of detrital layers in the composite profile, monthly distribution of River Ammer flood events with daily runoff  $\geq 100$  (n=38) and  $\geq 125$  m<sup>3</sup>/s (n=17), and monthly precipitation distribution measured at the Meteorological Observatory Hohenpeißenberg approx. 20 km southwest of Lake Ammersee (blue line) within 1926 and 1999.

For evaluating the relation between flood layers and high-magnitude floods the 38 strongest floods during the instrumental period were sub-divided into three classes with mean daily runoff (3)  $\geq 150 \text{ m}^3/\text{s}$  ( $n=11$ ), (2)  $\geq 125 \text{ m}^3/\text{s}$  ( $n=17$ ), and (1)  $\geq 100 \text{ m}^3/\text{s}$  ( $n=38$ ) (hereafter all daily runoff information refer to mean daily runoff). Recurrence time of floods in class 3 is 6.8 years, while it is 4.4 and 2.0 years for classes 2 and 1, respectively. Except the November 1944 flood, all floods with a daily runoff  $\geq 125 \text{ m}^3/\text{s}$  occurred between May and August indicating spring and summer as major flood seasons (Fig. 2.7). This pattern does not change much when all floods  $\geq 100 \text{ m}^3/\text{s}$  (LfU, 2007) are considered (Fig. 2.7). As confirmed by previously published data, floods of this magnitude (Ludwig et al., 2003), monthly precipitation (Meteorological Observatory Hohenpeißenberg), and seasonality of detrital layers, all show a distinct maximum for spring and summer. For eight of the 11 floods (73%) with a daily runoff  $\geq 150 \text{ m}^3/\text{s}$  and 12 of the 17 floods (71 %) with a daily runoff  $\geq 125 \text{ m}^3/\text{s}$  corresponding spring-summer detrital layers have been found in the sediment record, respectively (Table 2.1; Fig. 2.8). Below  $125 \text{ m}^3/\text{s}$  daily runoff the number of floods leading to detrital layer deposition clearly decreases. Only two out of 21 floods with a daily runoff between 100 and  $125 \text{ m}^3/\text{s}$  are reflected in the sediment record (Table 2.1). This suggests that a daily runoff of approx.  $125 \text{ m}^3/\text{s}$  represents a threshold below which the deposition of a flood layer becomes less likely. The apparent lack of a relationship between flood magnitude and flood layer thickness (Fig. 2.8) suggests complex nonlinearities in the erosion-transport-deposition process cascade (e.g. Lamb and Mohrig, 2009) which require further investigations.

Such problems might also explain the lack of detrital layers corresponding to the July 1966 and August 1970 floods with  $\geq 125 \text{ m}^3/\text{s}$  daily runoff. Probably, lake internal currents led to an inhomogeneous distribution of detrital material on the lake floor resulting in a lack of deposition at the coring sites. This can only be verified by a denser net of surface cores in order to obtain an improved spatial view on the distribution of detrital layers on the lake floor. Two other spring-summer floods (August 1929; May 1940) that are not recorded in the sediment are likely missed because of sediment disturbances in the relevant core sections. The November 1944 flood likely is not recorded because after three weeks of daily surface temperatures below  $0^\circ\text{C}$  (Meteorological Observatory Hohenpeißenberg) the soil surface was frozen during the time of the flood triggering rainfall on November 22<sup>nd</sup>/ 23<sup>rd</sup> impeding soil erosion in the catchment and detrital matter flux into the lake.

Besides the possibility of lacking detrital layers for some floods  $\geq 125 \text{ m}^3/\text{s}$ , also ten floods below  $125 \text{ m}^3/\text{s}$  led to the deposition of a detrital layer. However, six of these layers are related to fall-winter floods which are not considered in our spring-summer flood time-series. The production of fall flood layers during lower magnitude floods might be explained by possible sediment re-distribution processes in the lake triggered by enhanced wave activity in fall. Additionally, two spring-summer layers are triggered by floods with 103 (thick layer D2) and  $106 \text{ m}^3/\text{s}$  daily runoff which is close to the defined threshold value of  $125 \text{ m}^3/\text{s}$  daily runoff. That leaves two spring layers triggered by floods clearly below  $125 \text{ m}^3/\text{s}$  daily runoff, which are only present in the proximal core (Table 2.1).

In conclusion, the detrital layer record in Lake Ammersee represents a time-series of spring-summer floods  $\geq 125 \text{ m}^3/\text{s}$  daily runoff. Four spring-summer floods of this magnitude are not detected in the sediment record (two due to sediment disturbances), while four flood layers are related to spring-summer floods below this threshold (two rather close to  $125 \text{ m}^3/\text{s}$  daily runoff) (Table 2.1).

**Figure 2.8.** Daily River Ammer runoff ( $\text{m}^3/\text{s}$ ) and seasonal detrital layer thickness (mm) from 1926 to 1999. Detrital layer thickness is from core AS07-P1 except when layers occur only in the proximal core AS07-P2.

#### 2.4.5 Detrital layer frequency and seasonal distribution (1545-1999)

To establish a long flood time-series back to 1545 only detrital layers occurring in core AS07-P1 have been considered, because core AS07-P2 reaches not further back in time than 1800. A total of 24 spring and 51 summer flood layers have been identified during this period. Average layer thickness is higher in summer (1.24 mm), than in spring (0.79 mm). Frequency distributions of spring-summer flood layers exhibit distinct maxima of summer and minor maxima of spring layers between 1545 and 1590, 1650 and 1730, and 1800 and 1840 (see Fig. 2.12). The 12 fall (0.70 mm), 5 winter (0.62 mm), and 5 not seasonally definable layers in AS07-P1 do not exhibit a clear distribution pattern.

Detailed micro-stratigraphic comparison of both sediment cores for the calibration period has shown that four detrital spring-summer layers (1978, 1959, 1937, 1935) found in the proximal core are not detected in the distal core located 6.2 km away from the Ammer river mouth and 1.8 km away for core AS07-P2 (Table 2.1). Consequently we have to expect a further underestimation of floods in this core which might affect the frequency distribution in case that the not recorded floods are clustered in periods of low flood layer frequency. Since the identified missing spring-summer layers in AS07-P1 during the calibration period are randomly distributed (Table 2.1), we are, however, confident that additional missing layers in the distal core do not significantly affect general trends in flood layer distribution.

#### 2.4.6. Detrital layers versus weather regime data

To evaluate large-scale atmospheric circulation effects on River Ammer runoff, the 17 strongest River Ammer flood events (daily runoff  $\geq 125 \text{ m}^3/\text{s}$ ) measured at gauge Weilheim (LfU, 2007) were compared with the occurrence of weather regimes over Europe from 1926 to 1999 (time covered by River Ammer runoff and weather regime data) using the weather regime (Großwetterlagen) catalogue by Gerstengarbe and Werner (2005). This catalogue deciphers the daily occurrence of 30 characteristic weather regimes over Europe starting 1881. The temporal offset between weather regime and river runoff was corrected using precipitation data from the Meteorological Observatory Hohenpeißenberg 20 km southwest of Lake Ammersee. Five weather regimes can be attributed to more than one of the highest 17 flood events. Three floods were caused each by Cyclonic Westerly (WZ) and High over the British Isles (HB) weather regimes. Two floods occurred during Cyclonic North-Westerly

(NWZ), Zonal Ridge across Central Europe (BM), and Cyclonic North-Easterly (NEZ) weather regimes (Figs. 2.9 and 2.10). The remaining five floods  $\geq 125 \text{ m}^3/\text{s}$  are related to Anticyclonic Westerly (WA), Trough over Central Europe (TRM), High Scandinavia-Iceland/Trough Central Europe (HNFZ), Anticyclonic South-Easterly (SEA), and Cyclonic South-Easterly (SEZ) weather regimes (Fig. 2.9).

**Figure 2.9.** Weather regimes triggering the 17 highest River Ammer flood events (daily runoff  $\geq 125 \text{ m}^3/\text{s}$ ) between 1926 and 1999. BM, Zonal Ridge Across Central Europe; HB, High Over the British Isles; HNFZ, High Scandinavia-Iceland/Trough Central Europe; NEZ, Cyclonic Northeastery; NWZ, Cyclonic Northwesterly; SEA, Anticyclonic Southeasterly; SEZ, Cyclonic Southeasterly; TRM, Trough Over Central Europe; WA, Anticyclonic Westerly; WZ, Cyclonic Westerly.

**Figure 2.10.** Expected pathway of cyclones during the main flood-prone weather regimes at Lake Ammersee: BM, HB, NEZ, NWZ, and WZ.

The summer and annual occurrences of these flood-prone weather regimes were compared with the detrital layer distribution in the longer core AS07-P1 between 1881 and 1999 (time span covered by varve and weather regime data). Particularly, annual frequencies of flood-prone weather regimes indicate similar trends as the detrital layer distribution (Fig. 2.11). The weaker agreement between summer flood-prone weather regimes and detrital layers might be due to difficulties regarding the seasonal segmentation of detrital layers (section 2.4.4). The link between flood prone-weather regimes and detrital layers seems weakened between 1920 and 1924, when additional detrital sediments enter the lake during construction work in the Ammer catchment for river channelization (Fig. 2.11).

**Figure 2.11.** Summer and annual flood layer frequency in core AS07-P1 between 1881 and 1999 on a 7-year running mean and frequency of flood-prone weather regimes (WA, WZ, NWZ, BM, HB, TRM, NEZ, HNFZ, SEA, SEZ) on a 249 and 999 point running mean, respectively. Detrital layers are marked by black bars. The different smoothing of the individual datasets was chosen to obtain a similar running mean with respect to the resolution of the records. The period of River Ammer channelization is shaded.

## 2.5. Discussion

### 2.5.1. Depositional processes of detrital layers

All three observed detrital microfacies types can be interpreted in terms of various depositional processes.

1. *Graded layers.* Grading, as well as abrasion and flame structures in the basal part of some layers, point to deposition of hyperpycnal underflows (Mangili et al., 2005). Because of the amount of suspended matter and water temperature, the inflowing water/sediment suspension is of higher density than the surrounding water body and moves as a density current along the lake floor (Sturm and Matter, 1978). During the spread within the lake basin the density difference between the water body and turbidity current diminishes, leading to a reduced transport capacity and consequently successively finer grain sizes (Siegenthaler and Sturm, 1991). This is reflected by grading and the proximal-distal pattern of detrital layer thickness in Lake Ammersee (Figs. 2.4 and 2.5).

2. *Silt/clay layers.* This layer type may form when fine silt and clay detrital material is transported into the lake by low-density currents. After entering the lake, the detrital grains are distributed in the water column as over- or interflow owing to the density of the inflowing current and that of the surrounding water body (Sturm and Matter, 1978; Mangili et al., 2005). As reflected in the hardly visible faint grading in some of these layers, the fine-grained material falls out of the water column and deposits within a few days on the lake bottom (Siegenthaler and Sturm, 1991). Alternatively, this layer type might reflect distal deposits of high density currents from which the coarser fraction already deposited (Mangili et al., 2005).

3. *Matrix-supported layers.* Various detrital and reworked sediment components as littoral calcite and diatom frustules and plant remains well-mixed within the sediment matrix form matrix-supported layers which are commonly thought to reflect major slope failures or debris flows. Correlation of the two studied cores, however, exhibits four matrix-supported layers in core AS07-P1 as distal deposits of graded layers. This confirms deposition after runoff events induced by underflows that have eroded material in the littoral zone of the lake. A special case is the thick matrix-supported layer D2. The processes triggering the deposition of this layer in summer 1993 are well documented by (1) observations made by the Weilheim water authorities in the lake catchment, (2) sediment trap data obtained near the location of our core AS07-P2 (Alefs, 1997), and (3) a sediment core obtained in October 1993. On July 17<sup>th</sup> 1993

a short (1.5 h) but intense local precipitation event (100 mm) caused a flood in the Ammer tributary Halbammer. This caused a break-up of the armor layer near the village Unternogg in close vicinity to the confluence of both rivers (Fig. 2.1) causing an incision of the riverbed of some meters and the collapse of a Halbammer bridge (Wasserwirtschaftsamt-Weilheim, personal communication, 2008).

In conclusion, microfacies analyses combined with instrumental runoff data from 1926 to 1999 (Table 2.1) prove that detrital layers in the Lake Ammersee sediments represent flood deposits (Sturm and Matter, 1978; Siegenthaler and Sturm, 1991) of the River Ammer. Alternative triggering mechanisms which are not directly related to floods (Mangili et al., 2005) are unlikely. No indications for debris flow deposits as observed in Lake Mondsee (Swierczynski et al. 2009) have been found in the studied sediment interval. The only observed trigger for detrital sediment flux into the lake basin not directly related to a flood is the construction work for channelizing the Ammer river from 1920 to 1924 (Alefs, 1997). Increased erosion led to a generally higher detrital input facilitating detrital layer deposition even during low-magnitude floods.

### 2.5.2. *Paleoclimatic implications*

Much of the current climate debate focuses on global temperature fluctuations. Less well constrained are the responses of the hydrological cycle and, particularly, extreme flood events to changes in climate boundary conditions. In addition to high-resolution temperature reconstructions (von Grafenstein et al., 1996, 1999), the Lake Ammersee sediment profile has a large potential for establishing long flood time-series at seasonal precision. Despite the still remaining lack of knowledge in understanding the entire cascade of processes from a flood to the deposition of a flood layer at a certain point in the lake basin, methodological improvements allowed to establish a reliable spring-summer flood layer time-series including an assessment of the uncertainties. We are confident that these data are sufficient to identify a distinct and apparently not stationary temporal pattern in the distribution of flood layers. Higher frequencies particularly of summer floods are observed for colder periods during the Little Ice Age. Similar observations have been made in historical flood time-series of River Main located approx. 200 km north of Ammersee (Glaser and Stangl, 2004), pointing to a wider regional significance of this finding.

**Figure 2.12.** (top) Flood layers (black bars) and annual flood layer frequency in core AS07-P1 on a 31-year running mean (black line). Residual  $\Delta^{14}\text{C}$  on a 1000-year running mean (red line) (Reimer et al., 2004). (bottom) Spring and summer flood layer frequencies on a 31-year running mean. Phases of lower solar activity during the Little Ice Age are highlighted by blue rectangles.

The flood layer frequency pattern coincides well for the period from 1545 to 1845 with reconstructed variations of residual  $\Delta^{14}\text{C}$ , commonly regarded as proxy for solar activity (Usoskin et al., 2003; Solanki et al., 2004). Particularly striking is the good agreement of maxima in summer and spring flood layers with residual  $\Delta^{14}\text{C}$  maxima during the Little Ice Age between 1545 and 1590, 1650 and 1730, and 1800 and 1840 (Fig. 2.12). The production of  $^{14}\text{C}$  in the upper stratosphere is higher during times of lower solar activity because more cosmic radiation can reach the Earth's atmosphere where it transforms  $^{14}\text{N}$  to  $^{14}\text{C}$ . Past atmospheric  $^{14}\text{C}$  concentrations ( $\Delta^{14}\text{C}$ ) have been reconstructed from tree rings and are expressed relative to the NBS oxalic acid standard activity in the  $\Delta$  notation (Stuiver and Polach, 1977). The residual  $\Delta^{14}\text{C}$  has been calculated from the IntCal04  $\Delta^{14}\text{C}$  dataset by removing a 1000-year running average from the record to reduce long-term geomagnetic field and reservoir effects. The residual  $\Delta^{14}\text{C}$  data does not extend in times younger than 1845 in order to exclude a bias through contamination by fossil-fuel burning (Reimer et al., 2004).

The coincidence between decadal-scale solar activity minima and cooling (Waple et al., 2002) particularly in Europe during the Little Ice Age in the 15<sup>th</sup> to 19<sup>th</sup> centuries (Mann, 2002), suggests large-scale climatic responses to solar forcing. However, since the physical processes behind the solar/climate link are not yet fully understood this remains a controversial discussion. Two hypotheses for possible amplifying mechanisms of the rather small variations in solar activity have been suggested (van Geel et al., 1999). (1) Variations in UV irradiance alter the stratospheric ozone production leading to changes in total radiative forcing and atmospheric circulation (Haigh, 1994, 1996). (2) Effects of solar magnetic variability on Earth's cosmic ray shielding alter the production of cloud condensation nuclei and consequently cloud cover and precipitation (Svensmark and Friis-Christensen, 1997; Svensmark, 2000). Although it is not straight forward to elaborate these feedback mechanisms in the climate system based on the Lake Ammersee flood record, the apparent link between high-magnitude floods and the occurrence of certain weather regimes in the Ammer catchment from 1881 to 1999 (Fig. 2.11) gives cause for further deliberations. Accepting that extreme floods are triggered by typical flood-prone weather regimes suggests that atmospheric circulation plays a major role in extreme flood initiation. Most of the high-magnitude River Ammer flood events in the observation period back to 1926 occurred in summer (Fig. 2.7) during particular weather regimes (Fig. 2.9). The increase in summer flood frequency during intervals of solar minima (Fig. 2.12), therefore, points to a more frequent occurrence of these flood-prone weather regimes and, thus, to changes in large-scale atmospheric circulation patterns. The increase in spring floods during times of lower solar activity (Fig. 2.12) might be additionally affected by stronger snow melt due to an increase in winter snowfall (Beniston and Jungo, 2002; McEwen, 2006). The coincidences between changes in flood frequency and both, solar activity and the occurrence of flood-prone weather regimes might be a further argument in support of the hypothesis of solar variability effects on atmospheric circulation patterns. However, this hypothesis has to be further tested by extending the flood layer record from Lake Ammersee further back in time to cover also older intervals of reduced solar activity in the Holocene. Moreover, comparable flood records from other regions are required to obtain a better regional view of flood frequency patterns.

## 2.6. Conclusions

All detrital layers in the Lake Ammersee sediment record have been proven as flood deposits. Microscopic analyses on petrographic thin sections identified spring and summer as the main seasons of flood layer deposition. Based on a precise varve chronology a 450-year flood layer time-series has been contributing to a better understanding of the effects of changing climatic boundary conditions on flood frequency. This underlines the potential of varved lake sediments as promising archives for establishing even longer flood records.

However, evaluating sediment archives necessitates considering the inherent data characteristics. On the one hand, sediment data cannot provide the same precision as instrumental or historical hydrological data in terms of time control, time resolution, and process quantification. On the other hand, only sediment archives reach far enough back in time to provide long-term information that cover even up to several climatic cycles including periods without any human interference on landscape evolution. These differences between instrumental and geological data obviously require different analytical approaches. It is a challenging task to link both approaches by bridging the different time concepts. A first step in this respect is to improve the time resolution of geological records by using annually laminated sediments.

In addition to the time scale issue, the complex processes involved in the deposition and preservation of a sediment archive must be better understood. Linking the Lake Ammersee flood layer record with instrumental Ammer flood data allowed, for the first time, defining an approximate threshold in spring-summer flood magnitude making the deposition of a flood layer likely. Moreover, we were able to assess the degree of ‘completeness’ of the flood layer record, *i.e.* to identify floods for which no corresponding flood layer has been found. The resulting number of flood layers was sufficient to determine changes in frequency trends of spring and summer floods representing the main flood seasons in the region. These frequency patterns were compared with proxy data of solar activity revealing an intriguing coincidence between periods of reduced solar irradiance and increased flood frequency. The additional observation that strong spring-summer floods correspond to the frequency of particular flood-prone weather regimes arises speculations about possible effects of solar variability on mid-latitude atmospheric dynamics.

This study is a first step in developing varved lake sediments as flood records at, for geological archives, unprecedented seasonal resolution. It particularly highlights the great

potential of this approach, but at the same time clearly points out the remaining problems in interpretation that have to be solved. Future work has to aim at a better understanding of the processes controlling flood triggered detrital matter erosion, transport, and deposition.

### **Acknowledgements**

This study is a contribution to the Helmholtz TERENO research project and the Helmholtz climate initiative REKLIM. The Wasserwirtschaftsamt Weilheim (WWA-WM) and the Bayerisches Landesamt für Umwelt (LfU) are acknowledged for providing River Ammer runoff data. Precipitation and temperature data from the Meteorological Observatory Hohenpeißenberg was supplied by the Deutscher Wetterdienst (DWD). We would like to thank D. Berger and G. Arnold (GFZ-Potsdam) for preparing high-quality thin sections, J. Zimmermann for his help with stable isotope measurements, and R. Niederreiter (UWITEC) for his support during sediment coring. A. Hendrich helped with the layout of Figures. Flood layer data files are available at <http://doi.pangaea.de/10.1594/PANGAEA.746240>.

#### **Highlights**

- We present a 5500 year record of 1573 flood layers in varved lake sediments.
- Integrating microfacies data from two sediment profiles shed light on depositional processes.
- These would have remained undetected using one sediment profile and without layer based analyses.
- Three shifts towards higher flood intensities occur at ~5500, ~2800, and ~500 varve years BP.
- Likely forcing mechanisms are gradual reduction in summer insolation and centennial-scale solar minima.

**Abstract.** Microfacies analyses and X-ray fluorescence scanning ( $\mu$ -XRF) at sub-mm resolution were conducted on the varved Mid- to Late Holocene interval of two sediment profiles (AS10<sub>prox</sub> and AS10<sub>dist</sub>) from pre-alpine Lake Ammersee (southern Germany) located in a proximal and distal position towards the tributary river Ammer. To shed light on sediment distribution within the lake, particular emphasis was (1) the detection of intercalated detrital layers and their micro-sedimentological features, and (2) intra-basin correlation of these event deposits. Detrital layers were dated by microscopic varve counting, verified by accelerator mass spectrometry  $^{14}\text{C}$  dating of terrestrial plant macrofossils.

Since ~5500 varve years BP, in total 1573 detrital layers were detected in either one or both of the investigated sediment profiles. Based on their microfacies, geochemistry, and proximal-distal deposition pattern, detrital layers were interpreted as River Ammer flood deposits. Earlier studies on flood layer seasonality have proven that flood layer deposition occurs predominantly during spring and summer, the flood seasons at Lake Ammersee. The flood layer record indicates three shifts in mean layer frequency and thickness at ~5500, ~2800, and ~500 varve years BP. Combining information from both sediment profiles allowed to interpret these shifts in terms of stepwise increases in mean flood intensity. Likely trigger of these shifts are gradual reduction in Northern Hemisphere orbital summer forcing and superimposed centennial-scale solar activity minima. Proposed response to this forcing is hemispheric cooling causing strengthened equator-to-pole temperature gradients and higher potential energy in the troposphere. This energy is translated into more intense cyclones, extremer rainfall events, and higher floods at Lake Ammersee.

### 3.1. Introduction

During river floods, detrital catchment material is eroded and transported in suspension by fluid turbulence into downstream lakes. In the water body the transport capacity of the inflowing turbidity current successively diminishes leading to the deposition of characteristic detrital layers on the lake floor (Sturm and Matter, 1978; Schiefer et al., 2011). Intercalated into annually laminated (varved) sediments the sequence of these flood layers provides an archive of flood activity that extends instrumental time-series for millennia even down to seasonal resolution (Czymzik et al., 2010; Swierczynski et al., 2012a). However, interpreting the succession of flood layers on the lake floor in terms of extreme environmental events requires a mechanistic understanding of the depositional processes. In addition to (1)

calibrating the detrital layer stratigraphy using instrumental data (Czymzik et al., 2010; Kämpf et al., 2012a), (2) monitoring individual turbidity currents in lakes and streams using current meters and turbidity sensors (Lambert et al., 1976; Gilbert and Crookshanks, 2009), and (3) inferring turbidity flow characteristics from model experiments (Lamb and Mohrig, 2009), the dynamics behind detrital layer deposition can be deduced from the micro-sedimentological features (microfacies) of the deposited layers themselves (Middleton, 1993; Lauterbach et al., 2012; Swierczynski et al., 2012b). Intra-basin correlation of complementary flood layers in two sediment profiles located in a proximal and distal position towards the tributary river of a lake enables interpretation of detrital layer microfacies with respect to sediment source and transport processes in the basin (Mangili et al., 2005; Wirth et al., 2011; Kämpf et al., 2012b).

Lake Ammersee in the pre-alpine region of southern Germany is an ideal location to build up a long time-series of flood-triggered sedimentation. Previous studies on oxygen isotopes from ostracods have proven the sediment record as a reliable paleoclimate archive enabling high-resolution temperature reconstruction (von Grafenstein et al., 1996, 1999). Extensive flysch, molasse, and late moraine formations in the meso-scale catchment provide abundant fine-grained detrital material for downstream transport into the gully shaped lake by only one main tributary, River Ammer (Fig. 3.1). Annual layering of the sediments enables both accurate detection and precise dating of detrital microfacies down to seasonal resolution (Czymzik et al., 2010). Calibration studies on two short sediment cores from Lake Ammersee using instrumental River Ammer runoff data verified the succession of detrital layers as an archive of major flood events (Czymzik et al., 2010). Due to this potential, two new long sediment profiles have been retrieved from Lake Ammersee located in a proximal and distal position towards the Ammer river mouth in order to establish a detailed Mid- to Late Holocene flood layer record and to examine changes in flood triggered detrital sedimentation in response to climate forcing.

### 3.2. Study Site

Lake Ammersee is a hardwater lake in the pre-alpine region of South Germany (48°00'N, 11°07'E) located 20 km southwest of Munich, at an elevation of 533 m (Fig. 3.1). The present day lake has a maximum water depth of 81.1 m and a surface of 47 km<sup>2</sup>. The north-south

orientated basin was eroded into Cenozoic sediments by the Ammersee lobe of the Isar-Loisach glacier during the last glaciation (Alefs, 1997).

**Figure 3.1.** Geographical position and geological sketch of the Ammer catchment including bathymetric map of Lake Ammersee with positions of sediment profiles AS10<sub>prox</sub> and AS10<sub>dist</sub>.

The main tributary of Lake Ammersee springs in the southwestern Ammergau Alps. Due to the region's karstic geology, the stream drains into a subterranean channel system to reach the surface again some hundred meters downstream – from there on named River Ammer. After leaving the Calcareous Alps in a northward direction the 84 km long river with a catchment of 709 km<sup>2</sup> flows through gently shaped flysch, molasse, and late moraine formations (Mangelsdorf and Zelinka, 1973) (Fig. 3.1). The river inflow into the lake was displaced by about 1 km to the southeast during construction works for River Ammer channelization between AD 1920 and 1924 (Czymzik et al., 2010).

Today, hydroclimate in the Ammer catchment is influenced by both maritime North Atlantic weather characterized by frequent westerly cyclonic disturbances and atmospheric blocking by continental high-pressure regimes (Petrow and Merz, 2009). Mean annual precipitation is approx. 1200 mm/year and shows a clear maximum during summer (Fig. 3.2). Due to the high relief difference of 1652 m between the highest point of the catchment in the northern Calcareous Alps (Kreuzspitze, 2185 m) and Lake Ammersee, precipitation shows a decreasing gradient from south to north. High water tables in the northern catchment and limited storage capacities of the alpine soils favor frequent floods through saturation excess overland flow (Ludwig et al., 2003) during precipitation maxima from late spring to summer (Fig. 3.2).

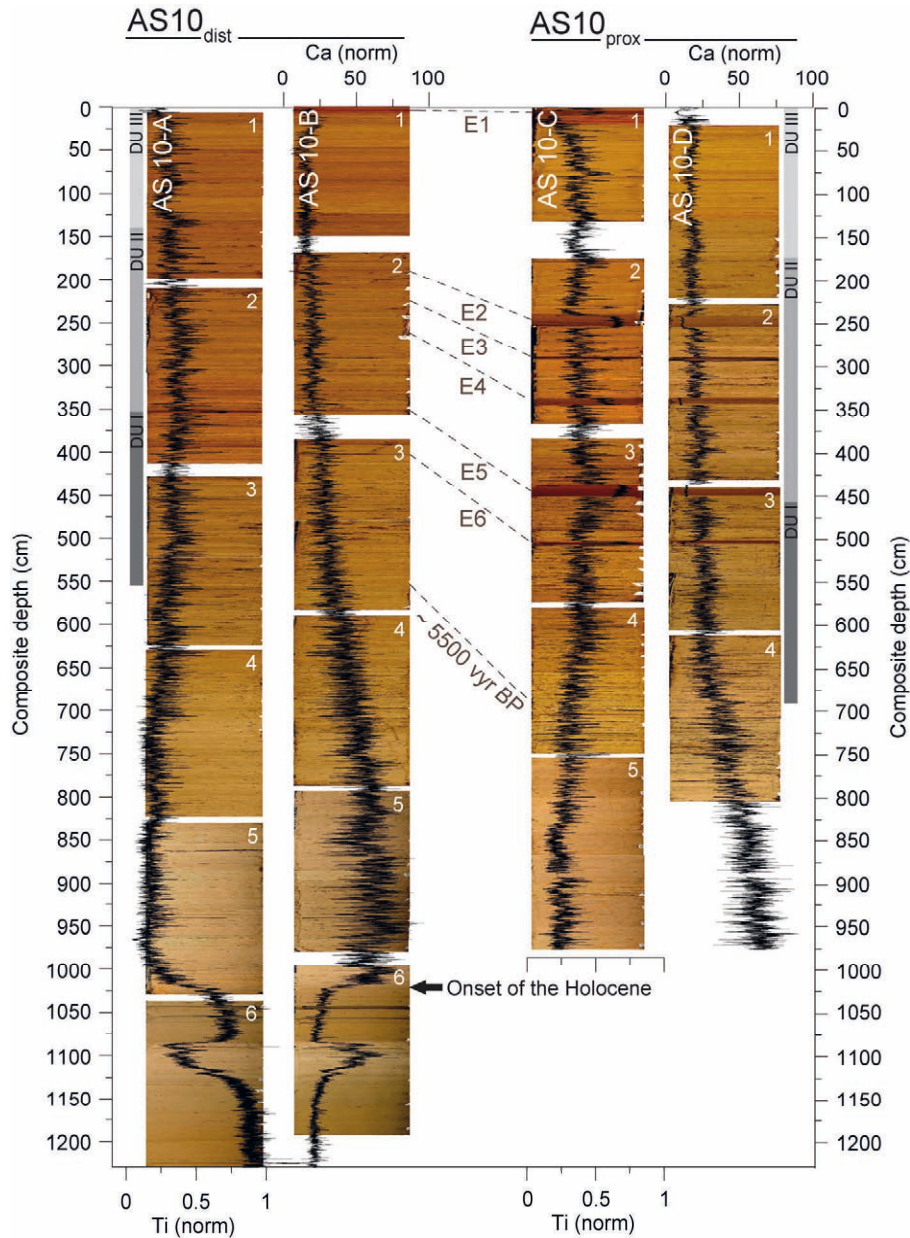

**Figure 3.2.** Daily River Ammer runoff from gauge Weilheim and precipitation from the Meteorological Observatory Hohenpeißenberg located approx. 20 km south of Lake Ammersee from AD 1926 to 1999. Since strong floods at Lake Ammersee occur after consecutive days of strong rainfall, precipitation data are shown on a 3-day running mean.

### 3.3. Methods

#### 3.3.1. Sediment coring and continuous varve profiles

At two locations in the deepest part of Lake Ammersee (Fig. 3.1), overlapping sediment cores consisting of 2 m segments were retrieved in July 2010 in a distance of a few meters using a modified UWITEC piston corer (Fig. 3.3). Sediment profile AS10<sub>prox</sub> (overlapping cores C and D) is located at a more proximal (4.4 km) and sediment profile AS10<sub>dist</sub> (overlapping

cores A and B) at a more distal position (6.2 km) towards the Ammer river mouth. Maximum sediment depth is 9.8 m for the proximal and 12.5 m for the distal coring location (Fig. 3.3). Retrieving overlapping sediment profiles at one coring location ensures continuity by bridging two consecutive core segments from one profile with a segment from the parallel profile (Fig. 3.3).

**Figure 3.3.** Composite profiles AS10<sub>prox</sub> and AS10<sub>dist</sub> exhibiting the correlation between individual core segments, the position of exceptional thick detrital layers E1 to E6, and the end of the investigated interval at ~5500 vyr BP. The lithostratigraphy is overlain by corresponding  $\mu$ -XRF data of the elements Ti (norm) and Ca (norm). Depositional units (DU) I to III and the onset of the Holocene are marked. Note that element data represent downcore composites and were not necessarily measured from the core segment on which they are plotted.

Continuous composite profiles AS10<sub>prox</sub> and AS10<sub>dist</sub> were constructed by visual correlation in the overlapping parts of parallel core segments (Figs. 3.3 and 3.4). A stratigraphical framework between the resulting composite profiles was established by intra-basin correlation of 107 macroscopic detrital layers of > 1 mm thickness (Fig. 3.4). These lithological markers provide on average every 50 years an isochronous correlation horizon.

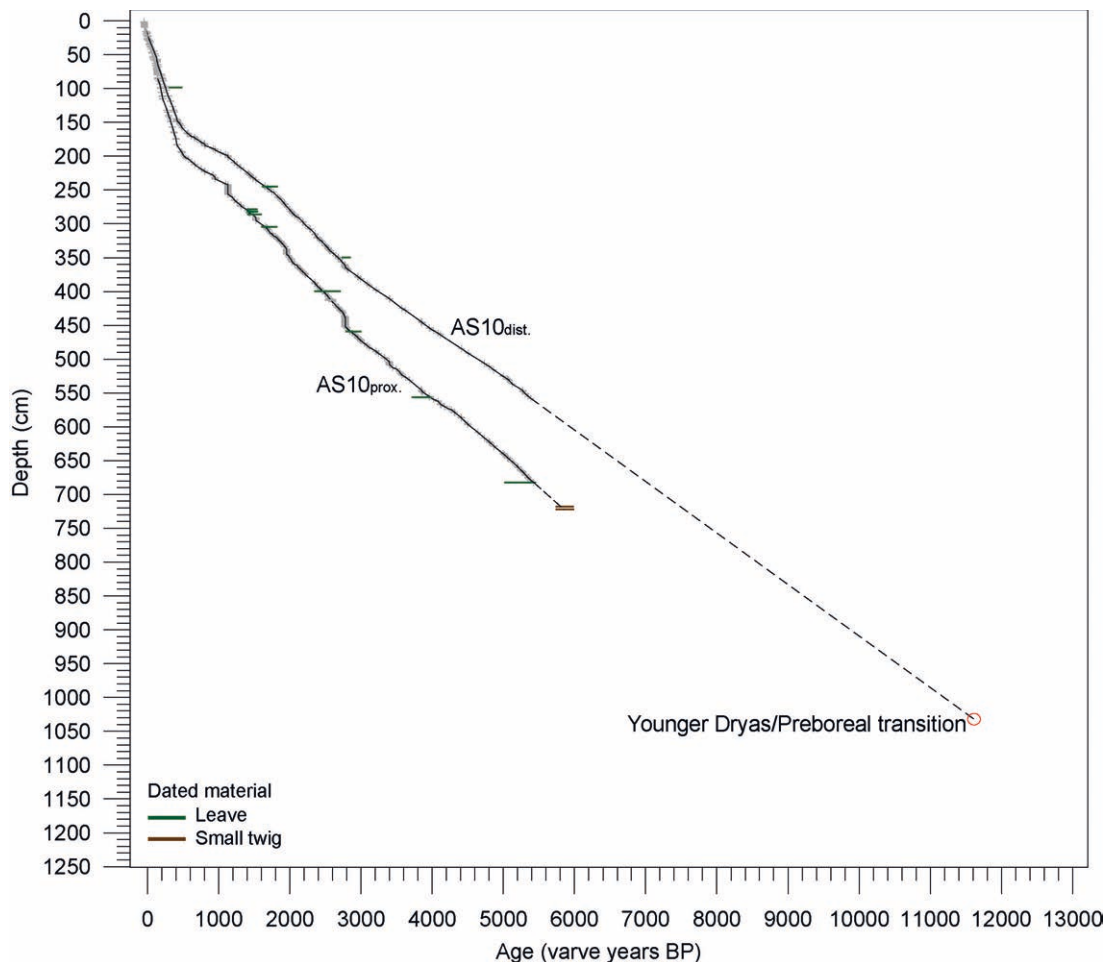

**Figure 3.4.** Correlation of sediment profiles. (a) Core-to-core correlation of parallel core segments using lithological marker layers and element profiles (Ti norm). (b) Intra-basin correlation of sediment profiles AS10<sub>prox</sub> and AS10<sub>dist</sub> based on macroscopic lithological marker layers.

### 3.3.2. Microfacies analyses

Detailed microfacies analyses of varve and detrital layer properties were performed on two overlapping series of large-scale petrographic thin sections from composite profiles AS10<sub>prox</sub> and AS10<sub>dist</sub>. Microscopic investigations were carried out applying a ZEISS Axiolab polarization microscope at 12.5x to 500x magnification under various light and optical conditions. Thickness measurements were performed at 25x magnification. Preparation of thin sections from soft and wet sediment blocks followed a standard procedure minimizing process-induced disturbances of sediment micro-structures and includes shock-freezing with liquid nitrogen, freeze-drying for 48 h, and epoxy resin impregnation under vacuum (Brauer and Casanova, 2001).

**Figure 3.5.** Age-depth model for sediment profiles AS10<sub>prox</sub> and AS10<sub>dist</sub> constrained by (1) varve dated ages of lithological marker layers (crosses), (2) AMS <sup>14</sup>C ages of 14 terrestrial plant macrofossils (bars indicate 2-σ error), and (3) dating of a chronomarker (onset of the Holocene) (von Grafenstein et al., 1999).

### 3.3.3. Chronology

The age model for the Lake Ammersee detrital layer record was produced (1) by continuous varve counting down to 175 cm in composite profile AS10<sub>prox</sub> and down to 142 cm in composite profile AS10<sub>dist</sub> and (2) by construction of a varve-based sedimentation rate chronology for the interval from 175 to 690 cm in AS10<sub>prox</sub> and from 142 to 357 cm in AS10<sub>dist</sub>. For the latter, varve thickness measurements were carried out in well-preserved sediment sections. Detrital layers in the sediment interval from 357 to 567 cm in AS10<sub>dist</sub> were dated by transferring ages of correlating deposits in AS10<sub>prox</sub>. Independent age control is provided by accelerator mass spectrometry (AMS) <sup>14</sup>C dating of 14 plant macrofossil samples. Of these samples, 9 are leaves and 2 are small twigs from AS10<sub>prox</sub> and 3 are leaves from AS10<sub>dist</sub> (Fig. 3.5). Conventional <sup>14</sup>C dates were calibrated to years before present (yr BP), *i.e.* AD 1950, applying the CALIB 6.0 program working with the INTCAL09 calibration curve and 2- $\sigma$  errors (Reimer et al., 2009).

### 3.3.4. X-ray fluorescence scanning

A set of major element data has been measured from the foil covered surface of splitted cores for composite profiles AS10<sub>prox</sub> and AS10<sub>dist</sub> at 200  $\mu$ m resolution (*i.e.* 5000 data points/meter) using an ITRAX X-ray fluorescence ( $\mu$ -XRF) core scanner (Cox Analytical, Sweden). The spectrometer has been equipped with a Cr tube and an energy-dispersive SDD detector (Croudace et al., 2006). To reduce sediment matrix effects and ensure predominance of the environmental signal (Francus et al., 2009), the X-ray beam (35 kV, 500  $\mu$ A, 10 s dwell time) has a width of 8 mm and is orientated parallel to sediment laminations. Continuous downcore element profiles were constructed through multi-parameter correlation of sedimentological and geochemical sediment properties in the overlapping parts (at least 10 cm) of the measured core segments (Fig. 3.4). Micro-XRF data reflect counts per measurement and element normalized (norm) against Cr<sub>inc</sub> representing relative changes in total element composition. Depth-based  $\mu$ -XRF data were transferred to the age scale by correlation with varve-dated lithological marker layers, 211 in AS10<sub>prox</sub> and 156 in AS10<sub>dist</sub> (Fig. 3.5). Combining high-resolution microfacies and  $\mu$ -XRF analyses allows evaluating the sedimentological and geochemical properties of each single sediment layer and enables better interpretation and quantification of the data (Brauer et al., 2009).

### 3.3.5. *CaCO<sub>3</sub> contents, mineralogy, and grain size distributions*

The six thickest detrital layers (E1 to E6) were additionally investigated for intra-layer architecture and composition using CaCO<sub>3</sub> contents, mineralogy, and grain size distributions. Varved intervals above and below each detrital layer were analyzed for comparison.

CaCO<sub>3</sub> contents were calculated from the total carbon and total organic carbon contents of freeze-dried and homogenized 1 cm sediment slices. Before measuring with an EA-CHNS element analyzer (Eurovector, Milan), aliquots of 3 µg were extracted from the original sample, and for total organic carbon analyzes pre-treated with 20 % HCl at 75°C. After combustion in excess oxygen at 1000°C, total carbon and total organic carbon contents were inferred based on the CO<sub>2</sub> and N<sub>2</sub> contents of the again reduced gases.

Semi-quantitative X-ray diffraction (XRD) analyses were carried out on homogenized bulk sediment samples using a Diffraktometer 5000 (Siemens, Karlsruhe) equipped with a 2 kW X-ray generator working with a Cu tube. The resulting X-ray diffraction pattern is detected by a graphite monochromator and represents the mineralogical composition of the analyzed material.

Grain size distributions of 2 cm sediment samples were measured using a Mastersizer 2000 laser diffraction granulometer (Malvern, Worcestershire). Sample preparation included combustion for 2 hours at 900°C in a muffle furnace to remove the organic fraction and treatment with a dispersant liquid. To ensure representativity of the results, five aliquots from each sample were measured and the final data given as the arithmetic mean of the single measurements.

## 3.4. Results

### 3.4.1. *Chronology*

The age-depth model for Lake Ammersee sediment profiles AS10<sub>prox</sub> and AS10<sub>dist</sub> was established back to 5510±161 varve years (vyr) BP. Based on the quality of varve preservation, the chronology can be subdivided into three chronological zones.

*Chronological zone A.* Back to 400±8 vyr BP (0-175 cm in AS10<sub>prox</sub>/0-142 cm in AS10<sub>dist</sub>) (Fig. 3.3), the chronology for both sediment profiles was constrained by two continuous

counts of distinct varves. Detrital layer seasonality was determined by the microstratigraphic position within an annual sedimentation cycle. A composite chronology was established using counts from the best preserved sediment profile and differs less than 2 % from two previous Lake Ammersee varve chronologies (Alefs, 1997; for details see Czymzik et al., 2010).

*Chronological zone B.* Due to poor varve preservation, a varve-based sedimentation rate chronology covers the time interval from  $400\pm 8$  to  $5510\pm 161$  vyr BP in AS10<sub>prox</sub> (175-690 cm sediment depth) and to  $2820\pm 81$  vyr BP in AS10<sub>dist</sub> (142-357 cm sediment depth) (Fig. 3.3). Years of detrital layer deposition in interpolated sediment intervals were determined based on the calculated sedimentation rate. Annual sedimentation rates have been determined by varve thickness measurements for 55 % of all varves, excluding detrital layers. Comparison of independent varve counts in intervals between two consecutive marker layers in AS10<sub>prox</sub> and AS10<sub>dist</sub> (Chapter 3.3.1) revealed a mean chronological error of less than 3 % and enabled to identify the best preserved sediment profile used for the composite chronology.

*Chronological zone C.* No varves are preserved in sediment profile AS10<sub>dist</sub> from  $2820\pm 81$  to  $5510\pm 161$  vyr BP (357-567 cm core depth). Detrital layers in this interval were dated by transferring ages of correlating deposits in AS10<sub>prox</sub> (Fig. 3.4).

The composite chronology was anchored to the absolute time-scale using a distinct detrital layer (D2) proven to be formed in June 1993 by sediment trap data (Alefs and Müller, 1999). The onset of the Holocene was defined by a distinct increase in calcite precipitation and a decrease in detrital sedimentation at 1023 cm depth in AS10<sub>dist</sub> (Fig. 3.3) and dated to 11590 yr BP (von Grafenstein et al., 1999) (Fig. 3.5). The varve chronology is in agreement with 13 AMS <sup>14</sup>C dates. One AMS <sup>14</sup>C date from fragmented leaf particles dated to  $340\pm 30$  cal. yr BP yielded a ca. 60 years too old age, likely due to redeposition of the material (Fig. 3.5).

#### 3.4.2. Sediment microfacies

The studied sediment interval comprises the upper 690 cm of profile AS10<sub>prox</sub> and the upper 567 cm of profile AS10<sub>dist</sub> (Fig. 3.3). Sediment microfacies are biochemical calcite varves and three types of intercalated detrital layers.

### 3.4.3. Varve microfacies

Characteristic for alpine hardwater lake environments (Swierczynski et al., 2012a), the fine laminated Lake Ammersee deposits (Alefs and Müller, 1999; Czymzik et al., 2010) consist of lighter calcite and darker organic layer couplets (Lotter and Lemcke, 1999) (Fig. 3.6). Calcite layers consist of endogenic precipitated whitish calcite crystals up to 20  $\mu\text{m}$  in size. Typical for low-Mg calcite in freshwater environments like Lake Ammersee (Czymzik et al., 2010) crystal habits are blocky polyhedral and simple rhombic (Folk, 1974; Brauer et al., 2008) (Fig. 3.6). Since calcite precipitation in the epilimnion of lacustrine systems is mainly induced by (1) pH increase due to photosynthetic uptake of dissolved  $\text{CO}_2$  by blooming phytoplankton and, (2) because of the retrograde solubility of calcite, during water temperature increase, calcite layers form from late spring to mid-summer (Kelts and Hsü, 1978). Dark organic layers are composed of amorphous organic debris incorporated in a matrix of littoral calcite and dispersed detrital grains. This material is likely eroded at the shoreline by wave activity in fall and redeposited within the lake (Fig. 3.6).

**Figure 3.6.** (left) Lake Ammersee calcite varves comprising calcite (white) and organic (black) layer couplets (thin section photograph under polarized light). (right) REM-images of (top) an organic layer, (middle) a calcite/organic layer boundary, and (bottom) a calcite layer.

### 3.4.4. Detrital layer microfacies and geochemistry

Microfacies analyses of the proximal and distal AS10 profiles reveal three main types of detrital microfacies: (1) graded layers, (2) silt/clay layers, and (3) matrix-supported layers (Fig. 3.7). Verifying microscopic observations, all detrital microfacies are accompanied by positive excursions of the elements Ti (Fig. 3.7), Si, K, and Fe, indicative of terrestrial detrital material in Lake Ammersee sediments (Czymzik et al., 2010).

**Figure 3.7.** Microscope images of detrital microfacies (polarized light) and corresponding  $\mu$ -XRF Ti (norm) data for (a) a graded layer, (b) a silt/clay layer, and (c) a matrix-supported layer.

1. *Graded layers* (mean/max. thickness: 1.3 mm/10.8 mm). Layers of this type are characterized by grading from coarse silt (mean grain size 30  $\mu\text{m}$ ) to clay ( $< 2 \mu\text{m}$ ). Some scattered fine sand grains are present in the base of thicker detrital layers. Most thinner graded layers are characterized by an upward fining (Fig. 3.7). Thicker layers of this facies show multiple upward and inverse grading patterns. The predominantly angular detrital grains show a sharp basal contact to the underlying sediment and in some cases an erosional base (Fig. 3.8).
2. *Silt/clay layers* (mean/max. thickness 1.5 mm/9.6 mm). The very fine, silt to clay, detrital grains that form this lithofacies exhibit no textural organization (Fig. 3.7).
3. *Matrix-supported layers* (mean/max. thickness: 0.7 mm/135 mm). Matrix-supported layers consist of detrital grains incorporated into a matrix of intraclasts of endogenic calcite both appearing in varying abundances. Plant debris and some littoral diatoms are dispersed throughout these layers (Fig. 3.7).

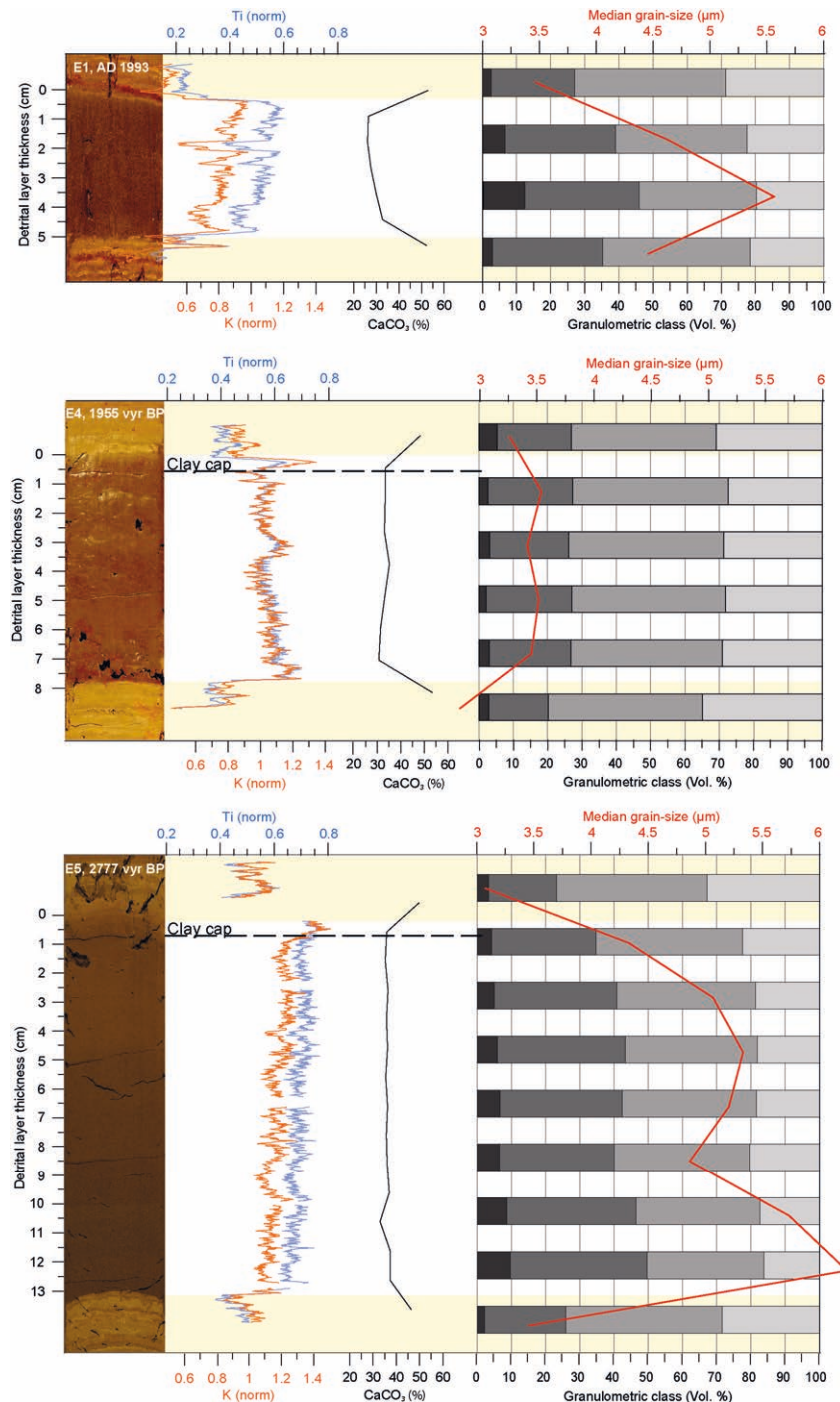

**Figure 3.8.** Microscope image of a detrital layer with an erosional base (polarized light).

The six thickest matrix-supported layers (E1-E6) deposited at AD 1993, AD 823 (1127 vyr BP), AD 425 (1525 vyr BP), BC 5 (1955 vyr BP), BC 827 (2777 vyr BP), and BC 1446 (3396 vyr BP) were additionally investigated for intra-layer architecture (Fig. 3.9). These layers are from profile AS10<sub>prox</sub> and vary in thickness between 30 and 135 mm. Thick matrix-supported layers show an increase in median grain size and reduced CaCO<sub>3</sub> contents (Fig. 3.9). Main mineral phases are quartz, calcite, and, to a small degree, dolomite. Compositional difference

(3) Shifts of Mid- to Late Holocene flood intensity in detrital layers from Lake Ammersee

to thin matrix-supported layers is a higher abundance and coarser grain size of the incorporated plant debris. The thickness of correlating deposits in AS10<sub>dist</sub> is on average a factor of 8.7 thinner. Five of these correlates are matrix-supported layers and one is a silt/clay layer.

**Figure 3.9.** Exceptional thick matrix-supported layers E1, E4, and E5 with corresponding  $\mu$ -XRF Ti and K (norm) data, CaCO<sub>3</sub> (%) contents, and median grain size values ( $\mu$ m). Granulometric classes (Vol. %) are: (black) coarse silt, 63 to 20  $\mu$ m; (dark gray) medium silt, 20 to 6.3  $\mu$ m; (light gray) fine silt, 6.3 to 2  $\mu$ m; and (white) clay, 2 to 0.01  $\mu$ m.

Intra-layer gradients of detrital elements, CaCO<sub>3</sub>, and grain size vary from layer to layer. Profiles of detrital elements and CaCO<sub>3</sub> contents show for 5 out of 6 layers no significant trend within the layer (E2, E3, E4, E5, E6). One layer (E1) indicates upward increasing values for detrital elements and decreasing CaCO<sub>3</sub> contents. Median grain size exhibits an upward fining for 3 layers (E1, E2, E5), no trend for layer E4, and an upward coarsening for layer E6. The thickness of layer E3 was too thin to extract more than one sample for grain size measurements. Five of six thick matrix-supported layers (E2, E3, E4, E5, E6) are covered by a clay cap of about 5 mm thickness (Fig. 3.9).

#### 3.4.5. Detrital layer stratigraphy

Since ~5500 vyr BP, in total 1573 detrital layers varying in thickness between 0.2 and 135 mm have been found in either one or both of the investigated Lake Ammersee sediment profiles. Before that time detrital layer deposition was very low in AS10<sub>prox</sub> and AS10<sub>dist</sub>. The detrital layer record can be subdivided into three depositional units (I-III) ranging from ~5500 to 2800 vyr BP, ~2800 to 500 vyr BP, and from ~500 vyr BP until today, characterized by different mean layer frequency and thickness (Figs. 3.10 and 3.11).

*Depositional unit I (~5500-2800 vyr BP).* In total 780 detrital layers have been found in this depositional unit. All of these layers were detected in AS10<sub>prox</sub>, but only 39 in AS10<sub>dist</sub>. Frequency of detrital layers is 29 layers/100 yr in AS10<sub>prox</sub> and 1 layer/100 yr in AS10<sub>dist</sub>. Mean detrital layer thickness is 0.4 mm in AS10<sub>prox</sub>. Due to the low sample size, no representative detrital layer thickness can be given for AS10<sub>dist</sub> (Figs. 3.10 and 3.11).

*Depositional unit II (~2800-500 vyr BP).* In comparison to depositional unit I, most conspicuous features of depositional unit II are thicker detrital layers in AS10<sub>prox</sub> and more frequent detrital layers in AS10<sub>dist</sub>. In total 633 detrital layers have been found in this depositional unit, 571 in AS10<sub>prox</sub> and 406 in AS10<sub>dist</sub>. Mean frequency and thickness of detrital layers is higher in AS10<sub>prox</sub> (24 layers/100 yr and 1.2 mm) than in AS10<sub>dist</sub> (17 layers/100 yr and 0.6 mm) (Figs. 3.10 and 3.11).

*Depositional unit III (~500 vyr BP–today).* The detrital layer stratigraphy in this depositional unit is characterized by an increase in mean layer thickness and frequency in AS10<sub>prox</sub> and AS10<sub>dist</sub>, compared to depositional unit II. In total 160 detrital layers have been found in this depositional unit, 150 in AS10<sub>prox</sub> and 110 in AS10<sub>dist</sub>. Mean detrital layer frequency and

(3) Shifts of Mid- to Late Holocene flood intensity in detrital layers from Lake Ammersee

thickness is higher in AS10<sub>prox</sub> (33 layers/100 yr and 1.4 mm) than in AS10<sub>dist</sub> (24 layers/100 yr and 1 mm) (Figs. 3.10 and 3.11).

Previous studies on a short Lake Ammersee sediment core (AS07-P1) from the position of AS10<sub>dist</sub> revealed 13 less detrital layers for depositional unit III (Czymzik et al., 2010). This difference does not change the detrital layer frequency distribution significantly and is due to poorer varve preservation in core AS07-P1 between ~400 and 100 vyr BP.

**Figure 3.10.** Frequency, thickness, and microfacies of detrital layers in AS10<sub>prox</sub> and AS10<sub>dist</sub> for depositional units I to III. For a better overview, detrital layer thickness is cut off at 10 mm.

**Figure 3.11.** Detrital layer deposition pattern for depositional units I to III (DU I-III). (a) Frequency of detrital layers (layers/100 yr), and (b) mean detrital layer thickness (mm).

#### 3.4.6. Differences in microfacies between AS10<sub>prox</sub> and AS10<sub>dist</sub>

Throughout the complete ~5500 years, 73 of 483 correlating detrital layers show different microfacies in AS10<sub>prox</sub> and AS10<sub>dist</sub>. 32 of these deposits are either graded or matrix-supported layers in the proximal profile correlating to silt/clay layers in the distal profile and 31 are graded layers in the proximal profile correlating to matrix-supported layers in the distal profile. Furthermore, eight matrix-supported layers in the proximal profile correlate to graded layers in the distal profile. One graded and one matrix-supported layer in the distal profile correlates to a silt/clay layer in the proximal profile (Fig. 3.10).

### 3.5. Discussion

#### 3.5.1. Mechanisms of detrital layer formation

The three detrital microfacies are interpreted in terms of different event-type deposition processes (Fig. 3.7).

1. *Graded layers.* Grading and a proximal-distal layer thickness and frequency pattern (Figs. 3.7 and 3.10) point to deposition of hyperpycnal turbidity currents commonly interpreted to reflect river floods (Sturm and Matter, 1978; Mulder and Alexander, 2001). The sediment/water effluent discharging into the lake is of higher density than the ambient water body and travels, keeping the transported material in suspension by fluid turbulences, as a subaqueous continuation of the river flow along the lake floor. Mixing at the turbidite/lake

water interface leads to a gradual decrease in turbulence affecting differential setting of the transported material (Siegenthaler and Sturm, 1991; Mulder and Alexander, 2001).

2. *Silt/clay layers.* The fine-grained nature of the deposited detrital material is indicative of meso- or hypopycnal flows (Sturm and Matter, 1978; Mulder and Alexander, 2001) (Fig. 3.7). After entering the lake, the detrital grains are dispersed into a buoyant plume far into the basin and distributed within the water column relative to the density of the travelling gravity current and that of the surrounding water body (Sturm and Matter, 1978). This is reflected by a rather homogenous occurrence of silt/clay layers throughout the basin (Fig. 3.10). The fine particles aggregate and fall out of the water column within few days (Siegenthaler and Sturm, 1991). Alternatively, as demonstrated by 32 silt/clay layers in AS10<sub>dist</sub> correlating to graded- or matrix-supported layers in AS10<sub>prox</sub>, this lithofacies might reflect distal deposits of high-density flows from which the coarser fraction already deposited (Mangili et al., 2005).

3. *Matrix-supported layers.* This microfacies reflects high-density currents in which particle interaction is the dominant transport mechanism and enhanced sediment concentrations inhibit graded setting of the material (Mulder and Alexander, 2001). The proximal-distal thickness pattern, incorporated littoral material, and 31 matrix-supported layers in AS10<sub>dist</sub> correlating to graded layers in AS10<sub>prox</sub> (Fig. 3.10) suggest deposition after Ammer flood events causing erosion of unconsolidated sediments.

A likely prerequisite for exceptional thick matrix-supported layers (Fig. 3.9) is additional sediment load in the tributary river system of Lake Ammersee. Observations in the Ammer catchment and sediment trap data from Lake Ammersee proved the exceptional thick matrix-supported layer deposited in AD 1993 to reflect a flood induced breakup of the armor layer in a River Ammer tributary (Czymzik et al., 2010). Additional trigger for thick matrix-supported layers might be slope failure in the river catchment.

To summarize, all detrital layers are very likely triggered by River Ammer floods. This interpretation is confirmed by calibration studies comparing the detrital layer record with instrumental River Ammer runoff data from AD 1926 to 1999. The agreement between flood events and flood layers proves the record to represent a time-series of high-magnitude River Ammer floods in spring and summer, the flood seasons in the Ammer catchment (Czymzik et al., 2010).

### 3.5.2. Uncertainty in flood layer time-series

Establishment of flood layer time-series might be biased by several processes.

Major source of uncertainty are missing flood layers, whether not deposited, not preserved, or not detected (Czymzik et al., 2010; Kämpf et al., 2012b). However, errors of this type can be to a degree detected, quantified, and minimized by comparison of detrital layers in two sediment profiles: For 1018 flood layers only present in AS10<sub>prox</sub>, missing correlates in AS10<sub>dist</sub> can be explained by reduced detrital sedimentation in more remote positions from the Ammer river mouth (Fig. 3.10). Dispersed detrital grains have been frequently observed in AS10<sub>dist</sub> at positions where detrital layers occur in AS10<sub>prox</sub>. For 72 flood layers only present in AS10<sub>dist</sub>, however, missing correlates in AS10<sub>prox</sub> are more difficult to explain. Mean thickness of these deposits in AS10<sub>dist</sub> is very thin (0.3 mm). Possible explanations for missing deposits in AS10<sub>prox</sub> might be (1) local erosion by the turbidity stream causing removal of already deposited material (Mulder and Alexander, 2001), (2) inhomogeneous spatial distribution of detrital material on the lake floor, and (3) sediment micro-disturbances. Sediment supply into Lake Ammersee from the western and eastern shores by other minor tributaries is negligible (Müller and Sigl, 1977) and, therefore, as trigger for these layers unlikely.

Since detrital layers in Lake Ammersee represent flood events of River Ammer, flood layers should successively get thinner as function of increasing distance towards the Ammer river inlet (Sturm and Matter, 1978; Mangili et al., 2005). Nevertheless, 225 correlating flood layers are either of equal thickness in both sediment profiles or even slightly thicker in sediment profile AS10<sub>dist</sub>. Equally thick deposits are on average very thin (0.3 mm). In the range of noise, thickness measurements for most of these correlates are not significant. Few slightly thicker flood layers in AS10<sub>dist</sub> might be explained by inhomogeneous spatial sedimentation and local erosion by the turbidity stream (Mulder and Alexander, 2001).

Human interferences in the lake catchment might obscure the climate induced flood layer signal through land use change modifying sediment mobility (Lauterbach et al., 2012). Located 4.4 km and 6.2 km away from the introductory source River Ammer, supply of detrital material to the locations of sediment profiles AS10<sub>prox</sub> and AS10<sub>dist</sub> requires strong floods (Czymzik et al. 2010). Human influences on sediment mobility might, therefore, predominantly amplify the amount of sediment transported into the lake during a flood, and thereby layer thickness, but should not significantly affect layer frequency.

As derived from pollen data, human activity in the Ammersee region first starts at ~4000 yr BP, intensifies synchronous with widespread deforestation and construction of a road net during the Roman Period at ~2000 yr BP, and reaches a maximum at ~1200 yr BP, when several monasteries were founded in the Ammer catchment (Kleinmann, 1995). The lack of synchronous changes in the flood layer record suggests that human contributions to flood layer deposition were likely minor (see Fig. 3.14). This result is in agreement with studies from lakes Lac du Bourget, Silvaplana, and Mondsee (Swierczynski et al., 2012b) suggesting that detrital layer deposition in larger lakes is not strongly affected by human impacts on sediment supply.

Changes in the availability of erodible detrital material in the catchment caused by varying local weathering rates are a further source of uncertainty in flood layer time-series. The Ammer catchment is covered by wide spread late moraine, flysch, and molasse formations since the last deglaciation that all provide abundant erodible fine material (Fig. 3.1). Therefore, changes in weathering rates are unlikely to influence the availability of erodible material at Lake Ammersee throughout the last 5500 years.

### 3.5.3. Mid- to Late Holocene changes in flood layer deposition

The Mid- to Late Holocene Lake Ammersee record is punctuated by three major shifts in mean flood layer frequency and thickness at ~5500, ~2800, and ~500 vyr BP of different manifestation in AS10<sub>prox</sub> and AS10<sub>dist</sub>.

After the onset of detrital layer deposition at ~5500 vyr BP, most significant feature of the flood layer record is a conspicuous increase in flood frequency in AS10<sub>prox</sub> resulting in a 29-fold higher flood layer frequency than in AS10<sub>dist</sub> (Fig. 3.11). The onset of flood layer deposition in AS10<sub>prox</sub> might be ascribed to an increase in mean flood intensity. Mean transport capacity of the water/sediment suspension in the lake at that time became sufficient to deliver sediment to the proximal coring location, but was not strong enough to transport sediment to the distal coring location (Fig. 3.12). Exceptions to this pattern are few flood layers in AS10<sub>dist</sub>. Correlating to the thickest deposits in AS10<sub>prox</sub>, these layers might be interpreted in terms of extreme floods (Fig. 3.10).

The second shift in flood layer deposition at ~2800 vyr BP is manifested by a 3-fold increase in flood layer thickness in AS10<sub>prox</sub> and a 17-fold increase in flood layer frequency in AS10<sub>dist</sub>

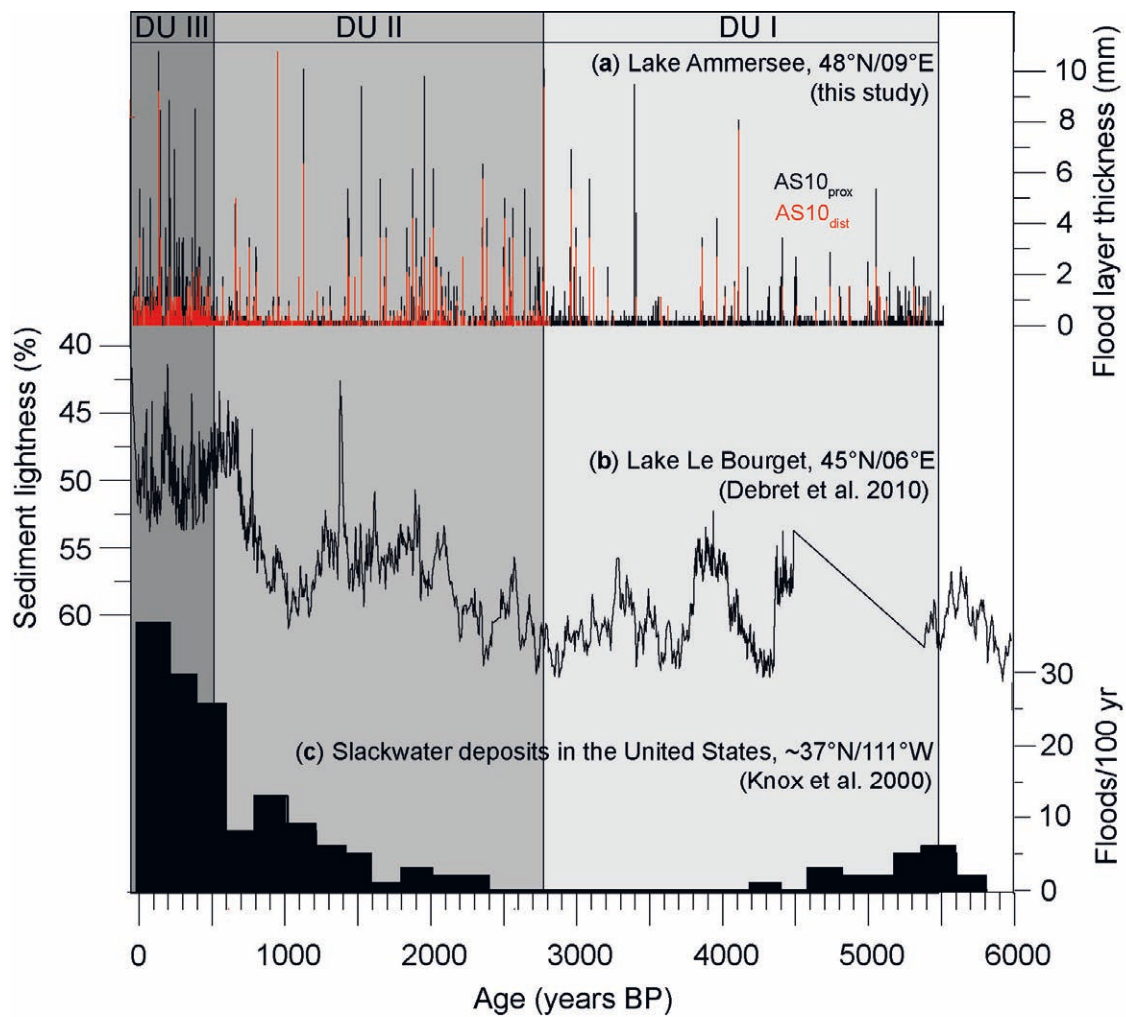

(Fig. 3.11). These changes in flood layer distribution might be explained by a further increase in mean flood intensity enhancing the amount of sediment transported to the proximal coring position and leading to a more frequent deposition of detrital material at the distal coring location (Fig. 3.12).

The third shift in flood layer deposition around  $\sim 500$  vyr BP is marked by an increase in flood layer thickness in AS10<sub>prox</sub> and AS10<sub>dist</sub> (Fig. 3.11), suggesting a further enhancement of mean flood intensity. The mean transport capacity of the flood triggered turbidity stream became sufficient to again enhance the amount of detrital material transported to the proximal and distal coring locations (Fig. 3.12).

To conclude, the emerging flood layer deposition pattern in Lake Ammersee sediments during the last  $\sim 5500$  years is best explained by three stepwise shifts towards higher flood intensities. Similar trends found in flood archives from mid-latitude regions around the globe point to a larger spatial significance of the signal (Fig. 3.13).

**Figure 3.12.** Schematic diagram of flood layer deposition in Lake Ammersee at the positions of sediment profiles AS10<sub>prox</sub> and AS10<sub>dist</sub> (a) before  $\sim 5500$ , (b) between  $\sim 5500$  and 2800, (c) between  $\sim 2800$  and 500 vyr BP, and (d) from  $\sim 500$  vyr BP until today.

**Figure 3.13.** Comparison of the (a) Lake Ammersee flood layer record (cut off at 10 mm) to mid-latitude paleoflood records. (b) Sediment lightness from Lake Le Bourget in the French Alps (Debret et al., 2010) and (c) paleofloods from slackwater deposits in Arizona and southern Utah, United States (Knox, 2000). Depositional units (DU) I to III are marked.

Today, flood events in the Ammer catchment are induced by cyclonic westerly weather regimes transporting moisture from the North Atlantic across continental Europe from late spring to summer (Czymzik et al., 2010). In order to increase the mean amount of deposited material on the lake floor after a flood event, rain intensity must have shifted towards extremer events. Anthropogenic influences as well as effects of changes in the availability of erodible material on flood layer deposition are likely of minor importance at Lake Ammersee (chapter 3.5.2).

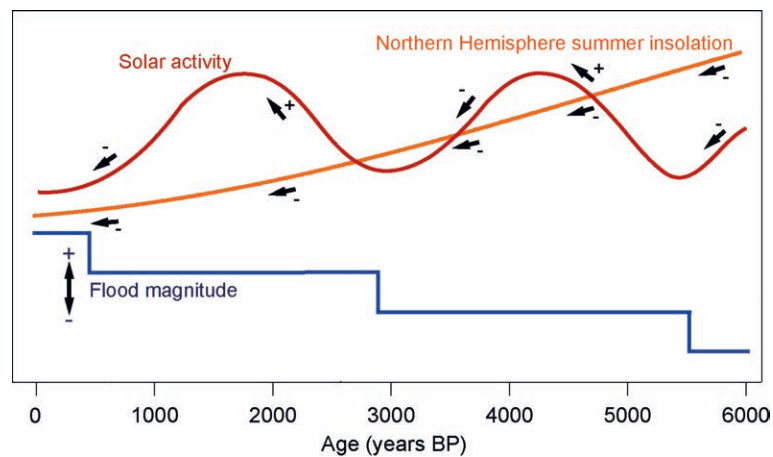

Westerly cyclone intensity is strengthened by hemispheric cooling acting to enhance potential energy in the troposphere by higher pole-to-equator temperature gradients and, consequently, strengthened baroclinicity (Gill, 1982; Raible et al., 2007; Lamy et al., 2010). Gradually reduced orbital forcing during Northern Hemisphere summer from the Mid-Holocene until today (Laskar, 1990) provoked progressive cooling in the Northern Hemisphere (Wanner et al., 2008) (Fig. 3.14). The regional relevance of this trend is verified by  $\delta^{18}\text{O}$  of precipitation reconstructed from ostracods in Lake Ammersee sediments, a proxy record of past air temperature (von Grafenstein 1996; 1999) (Fig. 3.14). Thus, orbital forcing might have contributed to the stepwise shifts towards increased mean flood intensity throughout the last ~5500 years.

However, as indicated by the stepwise increasing character, the recorded shifts in flood magnitude throughout the Mid- to Late Holocene are unlikely to be triggered by gradual changes in orbital forcing alone (Fig. 3.14). Timing of shifts in flood intensity coincides with centennial-scale solar minima (Hallstatt minima) (Damon and Sonett, 1991), as reflected in the low-pass filtered record of total solar irradiation (Steinhilber et al., 2009) (Fig. 3.14). A solar influence on climate has been repeatedly proposed based on correlations between paleoclimate records and solar activity. Hypothesized mechanism is a large change in UV radiation affecting polar vortex activity by modification of ozone chemistry and heating in the stratosphere. These disturbances communicate downwards to the surface via wave-mean flow interactions to influence position and strength of the tropospheric westerly storm tracks from winter to early spring (Gray et al., 2010; Martin-Puertas et al., 2012). In addition, shifts towards higher flood intensity at Lake Ammersee are in broad agreement with phases of higher lake level in central Europe interpreted to reflect wetter conditions (Magny, 2004) and cooling in the North Atlantic realm (Denton and Karlén, 1973; Bond et al., 2001; Magny, 2004; Mayewski et al., 2004) (Fig. 3.14). Records of aeolian sand flux in raised bogs from southwest Sweden offer information on increased storminess in the Northern Hemisphere at ~5500, ~2800, and ~500 yr BP (de Jong et al., 2006) (Fig. 3.14). These coincidences might associate the recorded shifts in flood magnitude at Lake Ammersee to strengthened westerlies and potentially hint to a solar influence on atmospheric circulation not only during winter, but also during summer. It is hypothesized that cryospheric processes in spring including sea ice cover of the Barents Sea and snow over Eurasia provide a memory allowing winter climate conditions, potentially affected by the Sun, to transfer into summer (Ogi et al., 2004).

**Figure 3.14.** Comparison of the Lake Ammersee flood layer time-series with selected Mid- to Late Holocene climate forcing and paleoclimate records. (a) Summer insolation (15. July) at 48°N (Laskar, 1990), (b)  $\Delta$  total solar irradiance (Steinhilber et al., 2009) on a 151-year running mean as low-pass filtered record of solar variability, (c) cold phases selected from the literature (see the figure for references), (d) aeolian sand influx (grains  $\text{cm}^2/\text{yr}$ ) reflecting wind strength (de Jong et al., 2006), (e)  $\delta^{18}\text{O}$  of precipitation inferred from benthic ostracods in Lake Ammersee sediments indicating air temperature (von Grafenstein et al., 1999), (f) flood layer frequency and thickness (cut off at 10 mm) in Lake Ammersee sediment profiles AS10<sub>prox</sub> and AS10<sub>dist</sub>. Timing of major human catchment interferences at Lake Ammersee is marked by arrows. Depositional units (DU) I to III are marked by gray shading.

On millennial time-scales, it appears that shifts in flood intensity at Lake Ammersee are induced by gradually reduced orbital summer forcing and centennial-scale solar activity minima affecting a strengthening of flood-prone atmospheric circulation patterns at the mid-latitude location of Lake Ammersee (Fig. 3.15). Proposed response to this forcing is hemispheric cooling enhancing potential energy in the troposphere by strengthened meridional temperature gradients. This energy is translated into intensified cyclonic disturbances, extremer precipitation events and stronger floods at Lake Ammersee.

**Figure 3.15.** Hypothesized forcing of shifts towards higher mean flood intensity at Lake Ammersee by gradually reduced Northern Hemisphere summer insolation and centennial-scale solar activity minima.

### 3.6. Conclusions

Tracing detrital layer microfacies in two sediment profiles located in a proximal and distal position towards the main tributary of Lake Ammersee and correlating them by means of a varve chronology shed light on flood triggered depositional processes within the lake. Based on their microfacies, geochemistry, and proximal-distal deposition pattern, detrital layers were interpreted as flood deposits of the main tributary River Ammer, predominantly deposited in late spring and summer.

In total 1573 flood layers were detected in the Lake Ammersee sediment record back to ~5500 vyr BP. The flood layer record is punctuated by three stepwise shifts in flood layer thickness and frequency at ~5500, ~2800, and ~500 vyr BP. Combining information from

both sediment profiles allowed to interpret these shifts in terms of stepwise increases in mean flood intensity.

Shifts towards higher flood intensities are likely triggered by gradual orbital and superimposed centennial-scale solar forcing. Likely atmospheric response to these forcing is latitude dependent cooling in the Northern Hemisphere that causes enhanced baroclinicity, stronger mid-latitude cyclones, and enhanced flood intensities at Lake Ammersee.

### **Manuscript in preparation**

**Modern societies are highly vulnerable to the effects of hydrological extremes like floods on lives and economy, and thermodynamic increase in atmospheric water vapor is expected to increase the likelihood of such events when Earth warms (Milly et al., 2002; Min et al., 2011). To adequately anticipate the response of floods to climate change it is crucial to understand the receptiveness of these events to natural climate forcing on short and long time-scales and on a regional basis (Knox, 1993; Mudelsee et al., 2003; Czymzik et al., 2010). Instrumental runoff time-series, however, rarely extend the last 100 years and are too short for satisfactory assessing flood responses to changing climate boundary conditions. Flood triggered detrital layers in annually laminated (varved) lake sediments provide natural flood records extending instrumental runoff time-series for millennia, down to seasonal resolution (Czymzik et al., 2010; Swierczynski et al., 2012a). Here, we report a 5500-year record of spring-summer floods based on the frequency of detrital layers in a varved sediment core from Lake Ammersee. Our findings demonstrate that recurrences of floods resemble variability in the East Atlantic-Western Russia (EA-WR) atmospheric pattern, which is commonly not considered for climate studies in this region, as well as decadal to millennial-scale changes in solar activity. Maxima in flood frequency correspond to the negative EA-WR phase and reduced solar activity. We propose a central role of changes in large-scale atmospheric circulation over Europe for the frequency of floods in the Ammersee region and suggest that these atmospheric changes, in turn, are likely influenced by solar variability throughout the past 5500 years.**

Extreme river floods have profound effects on society and environment (IPCC, 2012). On seasonal to multi-decadal scales, flood variability in Europe has been repeatedly linked to the prevalent phase of the North Atlantic Oscillation (NAO) (Hurrell, 1995) influencing low-frequency atmospheric circulation, regional precipitation and temperature (Rimbu et al., 2002; Moreno et al., 2008). Much less attention has been paid to hydrometeorological effects of other prominent atmospheric modes like the EA-WR pattern, a zonal symmetric seesaw of atmospheric pressure with centers of action over Western Europe and North of the Caspian Sea (Fig. 4.1) (Barnston and Livezey, 1987; Krichak and Alpert, 2005). Variations of these atmospheric patterns, in turn, are affected by various climate forcing (Nichols and Huang, 2012; Martin-Puertas et al., 2012). Enhanced radiative forcing caused by global warming increases atmospheric water-holding capacity and is expected to enhance the likelihood of stronger floods (Milly et al., 2002; Min et al., 2011). Natural climate variability may affect the frequency and magnitude of such events on time-scales from years to millennia (Knox, 1993; Mudelsee et al., 2003; IPCC, 2012). To date, however, understanding of flood responses to varying climate boundary conditions is limited due to the scarcity of hydrological data in space and time (IPCC, 2012). Exploring paleoclimate archives like varved lake sediments helps to fill this gap in knowledge offering precise dated time-series of flood variability for millennia, at seasonal resolution (Czymzik et al., 2010; 2012a; Swierczynski et al., 2012a).

**Figure 4.1. East Atlantic-Western Russia (EA-WR) atmospheric pattern and Lake Ammersee.** Schematic sketch of pressure anomalies for the negative phase of the EA-WR atmospheric pattern projecting lower pressure over Western Europe and higher pressure north of the Caspian Sea. (inset) Bathymetric map of Lake Ammersee with positions of sediment profile AS10<sub>prox</sub> and the Ammer river inlet.

Here, we provide a ~5500-year record of recurrences of major floods applying the frequency of detrital layers intercalated into a varved sediment profile from pre-alpine Lake Ammersee in southern Germany (48°00'N, 11°07'E, 533 m above sea level) (Fig. 4.1). During river floods, detrital catchment material is eroded and transported in suspension by fluid turbulence into downstream lakes. In the water body the transport capacity of the inflowing turbidity current successively diminishes leading to the deposition of detrital layers on the lake floor (Fig. 4.2) (Sturm and Matter, 1987; Mulder and Alexander, 2001).

**Figure 4.2. Lake Ammersee flood layers.** (a) Aerial photographs of Lake Ammersee during normal conditions and on 23.5.1999, one day after the crest of the Whitsun flood (22.5.1999; daily mean River Ammer runoff 535 m<sup>3</sup>/s) exhibiting large amounts of suspended sediments in the water column deposited as a conspicuous flood layer of 10 mm thickness (Czymzik et al., 2010). Red arrows indicate viewing directions. The locations of sediment core AS10<sub>prox</sub> and the Ammer river mouth before channelization between AD 1920 and 1924 are marked. (b) Core photograph of Lake Ammersee sediments showing lighter calcite varves and darker flood layers. (c-e) Micrographs (polarized light) of flood layer microfacies in Lake Ammersee sediments overlain by  $\mu$ -XRF Ti (normalized) data showing (c) a graded layer, (d) a silt/clay layer, and (e) a matrix-supported layer.

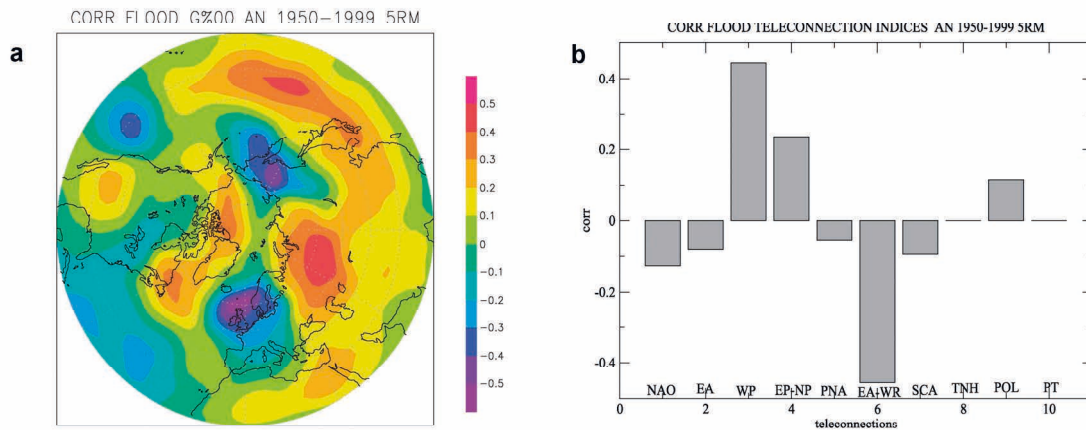

Today, major floods in the Ammer catchment are generated by exceptional cyclonic rainfall events from late-spring to summer (Czymzik et al., 2010). High water tables in the northern catchment and low water holding capacity of the alpine soils favor direct translation of

extreme precipitation events into floods by saturation excess overland flow. Late moraine, flysch, and molasse formations in the lake catchment provide abundant erodible fine material for downstream transport into the gully shaped lake by only one main tributary, River Ammer (Czymzik et al., 2012a).

From two Ammersee sediment profiles along a proximal-distal transect, the one closer (~4.5 km) to the Ammer river mouth (AS10<sub>prox</sub>) has been selected for flood reconstruction because of its more complete flood layer record (Czymzik et al., 2012a). The detrital layer time-series was constructed conducting complementary microfacies and X-ray fluorescence analyses (200 µm step size) on sediment profile AS10<sub>prox</sub> allowing reliable detection of even fractions of a mm thick sediment layers based on their sedimentological and geochemical properties (Czymzik et al., 2012a). Detrital layers were dated by varve counting and their position within an annual sedimentation cycle at seasonal resolution back to 400±8 vyr BP and, due to poorer varve preservation, by means of a varve-based sedimentation rate chronology at annual resolution from 400±8 to 5510±161 vyr BP, in agreement with 14 accelerator mass spectrometry <sup>14</sup>C dates (Czymzik et al., 2012a).

In total 1501 detrital layers varying in thickness between 0.19 and 135 mm (mean thickness 0.9 mm) were deposited during the past ~5500 years. These layers form three types of detrital microfacies explained in terms of fluxes of detrital catchment material into the lake after extreme runoff events (Fig. 4.2c-e) (Sturm and Matter, 1978; Mulder and Alexander, 2001; Mangili et al., 2005). Distinct Ti peaks for all detrital layers confirm this interpretation, indicative of terrestrial detrital material in Lake Ammersee sediments (Fig. 4.2c-e) (Czymzik et al., 2012a). River Ammer has been proven as source of the detrital material by the intra-basin deposition pattern of correlating flood layers (Czymzik et al., 2012a). Calibration studies with instrumental River Ammer runoff data confirmed the succession of flood layers to represent a time-series of major River Ammer floods during spring and summer (Czymzik et al., 2010). We consider the annual flood layer succession of the complete ~5500 years to represent a significant flood time-series during spring and summer, the flood season in the Ammer region (Czymzik et al., 2010), because 89 % of all flood layers in the seasonally resolved section back to ~400 vyr BP are deposited in these seasons (Czymzik et al., 2012a). A substantial human impact on flood layer deposition at Lake Ammersee can be ruled out since we do not observe an increase in detrital sedimentation synchronous to major human interferences in the Ammer catchment (Czymzik et al., 2012a).

**Figure 4.3. Relationship of flood layer frequency to 500 mb geopotential height anomalies and teleconnection patterns.** (a) Correlation between flood layer frequency and annual mean 500 mb geopotential high (Kalnay et al., 1996) for the period AD 1950-1999. (b) Correlation of annual flood frequency and annual indices of atmospheric teleconnection patterns for the same period. All datasets were filtered with a 5-year running mean prior to the analyses.

For identifying flood-prone large-scale atmospheric circulation at Lake Ammersee, we correlated annual flood layer frequency and annual mean 500 mb geopotential height both filtered with a 5-year running mean for the period AD 1950-1999 using each grid-point of the NCEP/NCAR reanalysis model (Kalnay et al., 1996), working at 2.5 lon x 2.5 lat resolution (Fig. 4.3a). The correlation map depicts a coherent northern hemispheric pattern. For periods of high (low) flood frequency, this pattern projects well on the negative (positive) phase of the EA-WR pattern (Fig. 4.3a). This result is consistent with correlations between flood layer frequency and selected teleconnection pattern indices for the period AD 1950-1999 revealing the highest negative correlation for the EA-WR pattern (Fig. 4.3b).

To test the relationship between flood frequency and the EA-WR atmospheric pattern in the longer term we computed sea level pressure (AD 1750-1999) (Küttel et al., 2010) and 500 mb geopotential height (AD 1766-1999) (Luterbacher et al., 2002) anomalies for years with a flood layer. Indicative of the negative EA-WR phase, both anomaly maps project lower pressure over Western Europe (Fig. 4.4).

**Figure 4.4. Flood layer frequency and atmospheric circulation. (a)** Sea level pressure (Küttel et al., 2010) anomaly pattern associated to years with a flood layer for the period AD 1750-1999. **(b)** 500 mb geopotential height (Luterbacher et al., 2002) anomaly pattern associated to years with a flood layer for the period AD 1766-1999.

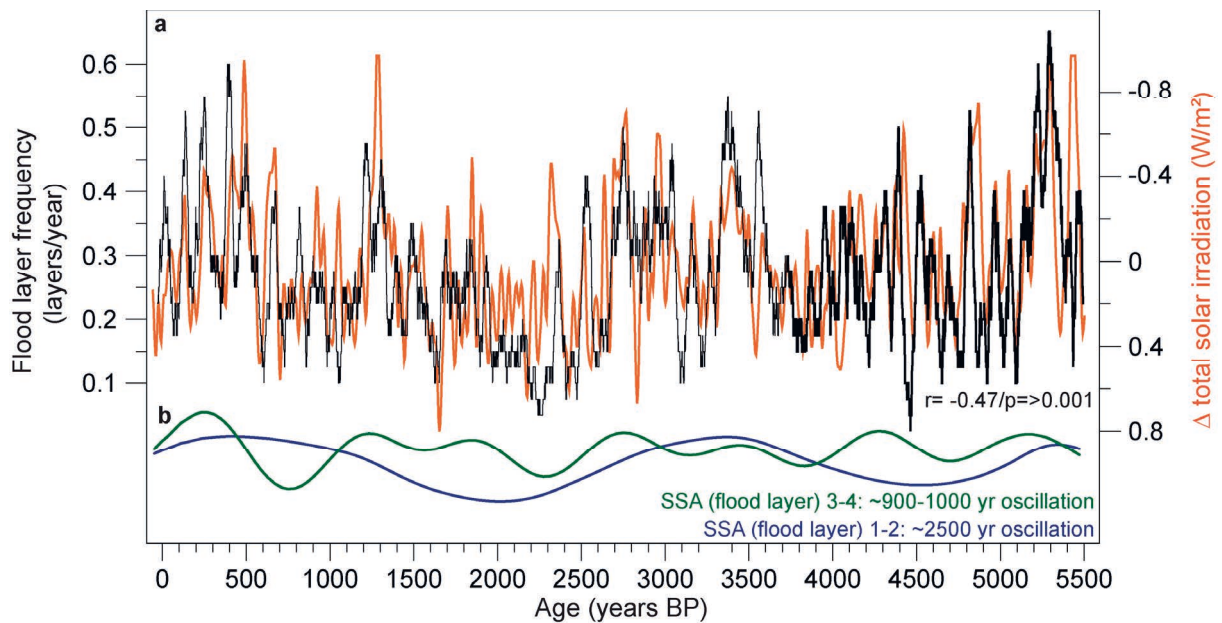

Instrumental mean daily River Ammer runoff data allow to investigate flood triggering atmospheric circulation at Lake Ammersee in more detail. We calculated mean 500 mb geopotential height anomalies 6, 3, and 0 days prior to River Ammer floods with a daily runoff  $\geq 130 \text{ m}^3/\text{s}$  for the period 1948-2006 using NCEP/NCAR reanalysis data (Fig. 4.5). The atmospheric circulation pattern represent an average of the circulation causing major River Ammer floods and reflect a Rossby wave-breaking phenomenon (Rivière et al., 2010). According to this, major floods at Lake Ammersee are predominantly triggered by atmospheric blocking over Eastern Europe and Rossby wave breaking by a high-pressure ridge over the Iberian Peninsula causing quasi-stationary orogenic precipitation in the Ammersee region by a low-pressure system transporting moisture from the North Atlantic to the northern Alps (Fig. 4.5). We propose that the EA-WR atmospheric pattern modulates the frequency of daily circulation patterns associated to floods in the Ammersee region.

**Figure 4.5. Mean atmospheric circulation during major River Ammer floods.** 500 mb geopotential height (m) (Kalnay et al., 1996) anomaly maps (a) 6 days, (b) 3 days, and (c) 0 days prior to River Ammer floods  $\geq 130 \text{ m}^3/\text{s}$  daily runoff for the period 1948-2006. The atmospheric circulation patterns represent an average of the circulation causing major River Ammer floods.

In addition, flood layer frequency trends throughout the past 5500 years resemble decadal-scale fluctuations in reconstructed total solar irradiance (TSI) (Steinhilber et al., 2009), increases in flood frequency correspond to reduced TSI ( $r=-0.47$ ;  $p<0.001$ ) (Fig. 4.6a). This linkage remains valid when the flood layer record is compared to multiple other solar activity proxy records (Fig. 4.7). While the influence of the Sun appears to be small on global scale, significant impacts were reported particularly for the mid-latitude areas of Europe and Asia (Martin-Puertas et al., 2012; Lockwood, 2012). Hypothesized mechanism amplifying the small changes in total solar irradiance is the large change in UV emission affecting polar

vortex activity by modification of ozone chemistry and heating in the stratosphere. These disturbances communicate downwards to the surface by mean wave activity flow to influence position and strength of the tropospheric westerly storm tracks in winter (Haigh, 1996; Gray et al., 2010). However, since the Ammersee flood record is representative for spring and summer, the correlation between flood layer frequency and solar activity suggests a solar influence on climate also for these seasons. Possible memory mechanisms transferring the potentially solar induced winter climate signal into summer might be cryospheric processes in spring like ice cover in the Barents Sea and snow in Siberia (Ogi et al., 2004).

**Figure 4.6. Flood layer frequency and solar activity during the past 5500 years. (a)** Frequency of flood layers in sediment profile AS10<sub>dist.</sub> and  $\Delta$  total solar irradiance (Steinhilber et al., 2009) filtered with a 40-year running mean. **(b)** SSA analysis of the filtered flood layer time-series revealing oscillations of 2500 years for SSA 1-2 and 900-1000 years for SSA 3-4.

In order to isolate longer-term quasi-periodic components, we applied singular spectrum analysis (SSA) (Ghil et al., 2002) to the 5500-year flood layer record filtered with a 40-year running mean. Paired eigenvalues 1-2 reveal a ~2500 year and paired eigenvalues 3-4 a ~900-1000 year oscillation (Fig. 4.6b). Both oscillations have been previously detected in the solar activity record (Dima and Lohmann, 2009) and suggest a solar influence on flood frequency not only on decadal, but also on up to multi-millennial time-scales.

**Figure 4.7. Agreement between flood layer frequency and multiple solar activity proxy records.** Graphic correlation between (a)  $^{10}\text{Be}$  flux in GRIP ice core (Vonmoos et al., 2006), (b) residual  $\Delta^{14}\text{C}$  (Reimer et al., 2004), (c) reconstructed sunspot number (Solanki et al., 2004), (d)  $\Delta$  total solar irradiance (Steinhilber et al., 2009), and (e) flood layer frequency filtered using a 40-year running mean.

This study highlights the great potential of detrital layers in varved lake sediments as long-term flood records at seasonal resolution allowing to deduce flood triggering climate mechanisms on time-scales from years to millennia. Based on robust correlations, our results implicate that the frequency of floods in the Ammersee region is not controlled by temperature, but by changes in large-scale atmospheric circulation over Europe. The additional link between flood frequency and the varying Sun suggests, in line with the hypothesis of a solar influence on mid-latitude tropospheric circulation via changes in UV emission, that these changes in atmospheric circulation, in turn, are likely induced by solar variability.

## (5) Summary

### 5.1 Main results

Primary scientific objectives of this PhD thesis were (1) to explore the potential of varved lake sediments as archives of flood activity and (2) to evaluate climate influences on frequency and magnitude of floods at Lake Ammersee.

To address these objectives a detrital layer record covering the last ~5500 years has been established from two varved Lake Ammersee sediment profiles retrieved in a proximal (AS10<sub>prox</sub>) and distal (AS10<sub>dist</sub>) position towards the main tributary River Ammer. The sedimentological and geochemical features of even microscopic detrital layers have been examined using microscopic microfacies analyses on petrographic thin sections and  $\mu$ -XRF measurements with a step size of 200  $\mu$ m. Detrital layers have been dated down to the season by varve counting and determination of the microstratigraphic position within an annual sedimentation cycle. The floating chronology is anchored to the absolute time-scale using a distinct detrital layer of which the deposition in June 1993 is confirmed by sediment trap data and validated by 14 AMS  $^{14}\text{C}$  dates from terrestrial plant macrofossils. Intra-basin correlation of detrital layers in both sediment profiles has been performed by means of varve chronology and stratigraphy (Czymzik et al., 2012a).

#### *5.1.1 The potential of detrital layers in varved Lake Ammersee sediments as flood archive*

**Detrital layers.** Detrital layers in Lake Ammersee sediment profiles form three types of microfacies: (1) *Graded layers* consist of clay to coarse silt detrital grains, predominantly organized in a thin upward fining sequence or in a thicker unit built-up by multiple regular and inverse graded beds. (2) *Silt/clay layers* are exclusively formed by very fine detrital grains exhibiting no clear indications of a textural organization. (3) *Matrix-supported layers* are composed of detrital grains and dispersed littoral debris incorporated into a matrix of endogenic calcite. All three detrital microfacies are explained by fluxes of detrital catchment material into the lake after extreme surface runoff events (Czymzik et al., 2010; 2012a).

Confirming the origin of the material, detrital microfacies are accompanied by distinct increases in the elements Ti, Si, K, and Fe, indicative of terrestrial detrital material in Lake Ammersee sediments (Czymzik et al., 2012a).

Due to a successive reduction of transport capacity in the water body, the thickness of flood deposits on the lake floor gets thinner, or deposition even ceases, as function of increasing distance towards the introductory source. Analyzing detrital layers in two sediment profiles along a proximal-distal transect towards the Ammer river mouth revealed 63 % more and 55 % thicker detrital layers in the proximal sediment profile. This proximal-distal deposition pattern enabled to trace River Ammer as source of the material (Czymzik et al., 2012a). Thus, from their microfacies, geochemistry, and proximal-distal deposition pattern, it can be inferred that the succession of detrital layers in Lake Ammersee sediments represents a time-series of River Ammer floods.

***Calibration of the flood layer stratigraphy using instrumental runoff data.*** In order to evaluate the flood time-series in terms of triggering mechanisms and completeness, and to confirm the microscopic determined layer seasonality, the flood layer record was calibrated with instrumental mean daily River Ammer runoff data from AD 1926 to 1999, the time-span covered by flood layer and runoff data (Czymzik et al., 2010).

First, this calibration showed that all layers are triggered by River Ammer floods and confirmed the microstratigraphic determined flood layer seasonality. For 15 of 22 flood layers the season has been determined exactly. Three flood layers designated as “summer” layers correspond to May floods and two designated “spring” layers correspond to February floods. Flood layer seasonality is defined by the position relative to the calcite layer. A spring flood layer is positioned directly under, and a summer flood layer above the calcite layer. The slight uncertainties in flood layer seasonality might be explained by inter-annual variability in the timing of calcite precipitation caused by varying onset and magnitude of summer warming. Further, two designated spring layers reflect a June flood. This uncertainty might be due to micro-erosion that displaced the thin calcite layer (Czymzik et al., 2010).

Second, comparing the flood layer record to instrumental River Ammer floods of different runoff thresholds allowed to define a kind of runoff threshold below which flood layer deposition becomes very unlikely and to evaluate the completeness of the flood layer record. 12 of 17 (71 %) of the strongest floods ( $\geq 125 \text{ m}^3/\text{s}$  daily mean runoff) are covered by spring-summer flood layers. For the remaining 5 floods  $\geq 125 \text{ m}^3/\text{s}$  no corresponding flood layer has been found (see the following paragraph for a discussion of possible biases in flood layer time-series). Below the threshold of  $125 \text{ m}^3/\text{s}$  the deposition of a flood layer becomes very unlikely. From 21 floods with a daily runoff between 100 and  $125 \text{ m}^3/\text{s}$  only 2 are represented by a flood layer (Czymzik et al., 2010).

However, including the latter two layers, the comparison also revealed 10 flood layers that are deposited by lower magnitude floods ( $< 125 \text{ m}^3/\text{s}$ ). Six of these layers are deposited during fall or winter and are not considered for our spring-summer flood time-series. The production of fall flood layers during lower magnitude floods might be explained by enhanced sediment redistribution due to wave triggered shoreline erosion in fall. Two of these layers are deposited in spring-summer and are triggered by floods close to the defined threshold value of  $125 \text{ m}^3/\text{s}$  daily runoff. Two are spring-summer layers only present in AS10<sub>prox</sub> related to a flood clearly below  $125 \text{ m}^3/\text{s}$  daily runoff (Czymzik et al., 2010).

To conclude, the flood layer stratigraphy in Lake Ammersee sediments represents a significant time-series of the frequency of spring-summer floods  $\geq 125 \text{ m}^3/\text{s}$  daily runoff. The lack of a clear link between the thickness of individual flood layers and flood magnitude suggests non-linearity in the erosion-transport-deposition process cascade (Czymzik et al., 2010).

***Uncertainty in flood layer time-series.*** Several processes might bias flood layer time-series. Main source are missing flood layers, whether not deposited, not preserved, or not detected. Comparison of detrital layers in two sediment profiles allows to a degree to detect, quantify, and minimize this type of error: For 1018 flood layers only present in AS10<sub>prox</sub>, missing correlates in AS10<sub>dist</sub> might be due to reduced detrital sedimentation in more remote positions from the Ammer river mouth. Dispersed detrital grains have been frequently observed in AS10<sub>dist</sub> at positions where detrital layers occur in AS10<sub>prox</sub>. For 72 flood layers only present in AS10<sub>dist</sub>, however, missing correlates in AS10<sub>prox</sub> are more difficult to explain. Mean thickness of these deposits in AS10<sub>dist</sub> is very thin (0.3 mm). Possible explanations for missing deposits in AS10<sub>prox</sub> might be (1) local erosion by the turbidity stream causing removal of already deposited material, (2) inhomogeneous spatial distribution of detrital material on the lake floor, and (3) sediment micro-disturbances. Sediment supply into Lake Ammersee from the western and eastern shores by other minor tributaries is negligible and, therefore, as trigger for these layers unlikely (Czymzik et al., 2012a).

Human interferences in the lake catchment might obscure the climate induced flood layer signal through land use change modifying sediment mobility. Located 4.4 km and 6.2 km away from the introductory source River Ammer, supply of detrital material to the locations of sediment profiles AS10<sub>prox</sub> and AS10<sub>dist</sub> requires strong floods (Czymzik et al., 2010). Human influences on sediment mobility might, therefore, predominantly amplify the amount

of sediment transported into the lake during a flood, and thereby layer thickness, but should not significantly affect layer frequency (Czymzik et al., 2012a).

As derived from pollen data, human activity in the Ammersee region first starts at ~4000 yr BP, intensifies synchronous with widespread deforestation and construction of a road net during the Roman Period at ~2000 yr BP, and reaches a maximum at ~1200 yr BP, when several monasteries were founded in the Ammer catchment. The lack of synchronous changes in the flood layer record suggests that human contributions to flood layer deposition were likely minor. In agreement with studies from lakes Lac du Bourget, Silvaplana, and Mondsee, this result might imply that detrital layer deposition in larger lakes is not strongly affected by human impacts on sediment supply (Czymzik et al., 2012a).

Further source of uncertainty in flood layer time-series are varying weathering rates changing the availability of erodible material in the catchment. The Ammer catchment is covered by wide spread late moraine, flysch, and molasse formations since the last deglaciation that all provide abundant fine detrital material for erosion and downstream transport into the lake during a flood. Therefore, changes in weathering rates are unlikely to influence the availability of erodible material at Lake Ammersee throughout the last 5500 years (Czymzik et al., 2012a).

### ***5.1.2 Climatic influences on flood frequency and intensity at Lake Ammersee***

***Mid- to Late Holocene changes in flood frequency.*** Correlation maps of flood layer frequency with 500 mb geopotential height from the NCEP/NCAR reanalysis model as well as with long-term sea level pressure and 500 mb geopotential height reconstructions project well on the East Atlantic-Western Russia (EA-WR) atmospheric pattern, while flood frequency at Lake Ammersee is enhanced when the EA-WR is in its negative phase. The EA-WR pattern is a zonal symmetric seesaw of atmospheric pressure over Europe. During its negative phase, low-pressure anomalies dominate over Western Europe and high-pressure anomalies dominate north of the Caspian Sea. This result is consistent with correlations between flood layer frequency and selected teleconnection pattern indices for the period AD 1950-1999 revealing the highest negative correlation for the EA-WR pattern. These correlations indicate that flood frequency at Lake Ammersee is apparently modified by the prevalent phase of the EA-WR atmospheric pattern (Czymzik et al., 2012b).

Furthermore, flood frequency resembles decadal to millennial-scale solar activity changes throughout the past ~5500 years, with more floods associated to reduced solar activity. A solar influence on Earth's climate variability has been repeatedly suggested based on correlations between climate variables and the activity of the Sun. While the influence of the Sun appears to be small on global scale, significant impacts were reported for mid-latitude areas of the European and Asian continents. Proposed mechanism amplifying the small changes in total solar irradiation is the large change in UV emission affecting polar vortex activity by modification of ozone chemistry and heating in the stratosphere. These disturbances communicate downwards to the surface by mean wave activity flow to influence position and strength of the tropospheric westerly storm tracks from winter to early spring. However, valid for spring and summer, the Lake Ammersee flood layer record suggests a solar influence on climate also for these seasons. It is hypothesized that cryospheric processes in spring including sea ice cover of the Barents Sea and snow over Eurasia transfer winter climate conditions potentially affected by the Sun into summer (Czymzik et al., 2012b).

Summarizing, the presented links suggest that flood frequency at Lake Ammersee in spring and summer is controlled by the prevalent phase of the EA-WR pattern, and that changes in this pattern might, in turn, might be influenced by solar variability throughout the past 5500 years (Czymzik et al., 2012b).

***Mid- to Late Holocene changes in flood intensity.*** Combining flood layer frequency and thickness data from AS10<sub>prox</sub> and AS10<sub>dist</sub> allowed to distinguish three shifts towards higher mean flood intensity at Lake Ammersee at ~5500, 2800, and 500 vyr BP (Czymzik et al., 2012a).

Strong floods at Lake Ammersee are triggered by cyclonic weather regimes from the North Atlantic during late-spring and summer (Czymzik et al., 2010). The intensity of such weather regimes is strengthened by hemispheric cooling acting to enhance potential energy and baroclinicity in the troposphere by higher pole-to-equator temperature gradients. Gradually reduced orbital forcing during Northern Hemisphere summer from the Mid-Holocene until today provoked progressive cooling. Hence, orbital forcing might have contributed to the stepwise shifts towards increased mean flood intensity throughout the last ~5500 years (Czymzik et al., 2012a).

However, as indicated by the stepwise increasing character, the recorded shifts in flood intensity are unlikely to be triggered by gradual reduction in orbital forcing alone. Timing of

shifts in flood intensity is synchronous with centennial-scale solar minima, as reflected in the low-pass filtered record of total solar irradiation. In addition, shifts towards higher flood intensity at Lake Ammersee are in broad agreement with phases of higher lake level in central Europe interpreted to reflect wetter conditions, cooling in the North Atlantic realm, and increased storminess in southwest Sweden. These coincidences presumably associate the shifts in flood intensity at Lake Ammersee to strengthened westerlies and potentially hint to a solar forcing of these changes (Czymzik et al., 2012a).

To conclude, stepwise shifts towards higher flood intensity at Lake Ammersee at ~5500, ~2800, and ~500 vyr BP are likely triggered by gradually reduced orbital summer forcing and centennial-scale solar activity minima. Proposed atmospheric response to this forcing is hemispheric cooling enhancing potential energy in the troposphere by strengthened meridional temperature gradients. This energy is translated into intensified cyclonic disturbances, extremer precipitation, and intensified floods at Lake Ammersee (Czymzik et al., 2012a).

## 5.2 Conclusions

Analyzing detrital layers in two varved sediment profiles from Lake Ammersee located in a proximal and distal position towards the main tributary River Ammer and correlating them by means of varve chronology enabled to establish a 5500-year record of flood triggered detrital sedimentation, down to seasonal resolution. Based on their microfacies, geochemistry, and proximal-distal deposition pattern, detrital layers were interpreted in terms of River Ammer flood deposits predominantly deposited in spring and summer. Calibration with instrumental River Ammer runoff data has proven the flood layer succession to represent a significant time-series of major River Ammer floods during spring and summer, the flood season in the Ammersee region. Interpretation of flood layer data in combination with reanalysis models and time-series analysis indicates that flood frequency and intensity at Lake Ammersee is not stationary, but modified by multi-causal climate forcing on time-scales from years to millennia influencing large-scale atmospheric circulation over Europe. These results challenge future projections that hypothesize an increase in floods when Earth warms based only on the assumption of an enhanced hydrological cycle.

A crucial prerequisite for establishing flood records from lake sediments is a favorable lake/catchment setting. Referring to this, various environmental features in the Ammersee setting can be addressed:

- Varved sediments enable to precisely detect flood layers and date them at seasonal precision by varve counting and the microstratigraphic position within an annual sedimentation cycle.
- A well-developed delta signifies River Ammer as an introductory source of detrital input into the lake throughout the past.
- The gully shaped basin morphology provides a well-defined deposition center for fluxes of detrital material into the lake. The absence of sub-basins that may prevent the turbidity stream to reach the coring locations reduces morphological effects on flood layer deposition and favors predominance of the climate induced flood signal.
- Detrital material is transported into Lake Ammersee by only one main tributary at its southern front side. This allows comparably undisturbed deposition of flood layers without competing lake internal currents and reduces erosion of already deposited detrital material. Additionally, the transport of detrital sediment into the lake by one main tributary enables to better trace the introductory source of flood deposits by their proximal-distal deposition pattern.
- Anthropogenic land use change, glacier fluctuations, and varying weathering rates might bias the climate driven flood layer signal by changing the availability of erodible detrital material in the catchment. These effects are likely of minor importance for detrital sedimentation at Lake Ammersee throughout the past 5500 years.
- Available local runoff and meteorological time-series allow to calibrate the flood layer record in terms of completeness as well as to disentangle climate and environmental impacts on flood triggered detrital sedimentation on a single layer basis.

The novel methodological approach for flood reconstruction combining microfacies analyses and high-resolution  $\mu$ -XRF measurements on two varved sediment profiles allowed to establish a paleoflood record of a new quality:

- Mean thickness of flood layers in the investigated Lake Ammersee sediments is 0.9 mm. Thus, most of these layers would have remained undetected using traditional geochemical, physical, and biological analyses on discrete samples.
- Investigating flood layers by means of microfacies analyses allows to interpret depositional processes by the micro-sedimentological features of the individual layer itself. This information enables an improved process-orientated understanding of flood layer deposition.
- Comparing flood layer time-series in two varved sediment profiles allows to reduce uncertainties in the chronology and biases in the flood layer time-series produced by missing layers. Correlation of flood layer microfacies in two sediment profiles enables to better infer depositional processes behind flood layer deposition and to trace the introductory source of the detrital material by the proximal-distal deposition pattern.
- To adequately calibrate the flood layer record with instrumental runoff data requires comparable time-concepts. The application of varved sediments reduces the usually decadal to multi-decadal resolution of lake sediment records to the season. This reduction of the time gap between geological and instrumental data allows to more directly compare both data.
- Seasonal varying soil moisture and vegetation cover in the lake catchment bias flood layer deposition by modifying sediment erosion and transport processes ([Istanbulluoglu and Bras, 2006](#)). To disentangle these environmental effects on flood layer deposition requires seasonal resolved records.
- Intra-annual climate variability affects regional flood characteristic with regard to triggering atmospheric circulation pattern ([Mudelsee et al., 2003](#); [Sivapalan et al., 2005](#)). To isolate this effect requires seasonal resolved chronologies.

### 5.3 Outlook

The presented results highlight the value of detrital layers in varved Lake Ammersee sediments for better understanding flood triggered detrital deposition in lakes and to deduce climate influences on flood frequency and intensity, but also point to potential for future studies.

Calibration of the Lake Ammersee flood layer stratigraphy with instrumental River Ammer runoff data reveals strong floods that are not represented by a flood layer. Comparing the results from both Lake Ammersee sediment profiles to each other and to instrumental Ammer runoff data allowed to deduce causes for missing layers. In few cases, however, these explanations remain rather speculative. Recently, at Lake Mondsee in upper Austria a holistic observation network was installed integrating in-depth monitoring in the catchment and the lake and a dense net of surface sediment cores. Preliminary results indicate that the observatory is able to trace, follow, and quantify flood-triggered fluxes of detrital material from the tributary river system using automated turbidity sensors and water samplers to the lake using sediment traps. A similar approach at Lake Ammersee will permit to better understand the complete cascade of processes behind flood layer deposition.

The results presented within this thesis suggest a solar influence on flood frequency and magnitude at Lake Ammersee. However, time-scale differences are presently a major source of uncertainty in paleoclimate studies. To investigate the solar/flood link in more detail requires proxy records based on the same chronology. First results on solar activity proxy  $^{10}\text{Be}$  in varved lake sediments showed the potential of these archives for solar activity reconstruction, but also pointed to potential biases through contamination with ‘old’  $^{10}\text{Be}$  by sediment redeposition (Berggren et al., 2009; Mann et al., 2012). Therefore, measuring  $^{10}\text{Be}$  in Lake Ammersee sediments might provide a more comprehensive insight into solar/flood relationships. However, it has to be assured that the samples for  $^{10}\text{Be}$  measurements are free of detrital material.

Keeping the time-scale issue in mind, analyses of  $\delta^{18}\text{O}$  from benthic ostracods in Lake Ammersee sediments allowed a high-resolution paleotemperature reconstruction for the period from 15500 to 5000 yr BP (von Grafenstein et al., 1999). Extending this record into the present based on the now existing varve chronology will allow to directly compare flood and temperature data for a better understanding of flood-triggering climate boundary conditions.

The Lake Ammersee paleoflood record shed light on regional flood triggering climate mechanisms working on multiple time-scales throughout the last 5500 years. However, flood-generating mechanisms vary in space and time (Petrow and Merz, 2009). A network of long flood time-series from varved lake sediments will help to better understand and predict flood triggering climate mechanisms in continental areas around the globe.

## Erklärung

Hiermit erkläre ich gemäß § 9 Abs. 7 der Promotionsordnung der Mathematisch-Naturwissenschaftlichen Fakultät der Universität Potsdam, dass ich die von mir vorgelegte Dissertation mit dem Titel

***Mid- to Late Holocene flood reconstruction from two varved sediment profiles of pre-alpine Lake Ammersee (southern Germany)***

selbstständig angefertigt, die benutzten Quellen und Hilfsmittel vollständig angegeben und wörtliche und sinngemäße Zitate als solche gekennzeichnet habe, sowie Tabellen, Karten und Abbildungen, die anderen Werken in Wortlaut oder dem Sinn nach entnommen sind, in jedem Einzelfall als Entlehnung kenntlich gemacht habe. Ich erkläre außerdem, dass diese Dissertation noch keiner anderen Fakultät oder Hochschule zur Prüfung vorgelegen hat; dass sie, abgesehen von den unten angegebenen Teilpublikationen, noch nicht veröffentlicht worden ist sowie, dass ich eine solche Veröffentlichung vor Abschluss des Promotionsverfahrens nicht vornehmen werde. Die Bestimmungen der Promotionsordnung sind mir bekannt.
